During the past several years the author has investigated the effects of x-radiation on normal dog brain. He found that myelin was comparatively radiosensitive, in contrast with the more radio-resistant brain cells. In addition, it was found that brain damage began when the myelinated nerves lost their optical properties (birefringency) even though they retained their outward physical form. The myelin degeneration which follows irradiation in dogs may require as long as one year to become evident.

Three patients presenting brain tumors who had received x-ray therapy demonstrated the same myelin sensitivity as was observed in dogs.

Thus, it is seen that structures which depend for their functional properties on a highly organized system of polar molecules lose their organized structure when bombarded with high energy radiation. The animal experiments show that when structural organization is gone, function is gone with it.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Harvey, V. K., and Luongo, E. P.: Physical Capacity for Work; Principles of Industrial Physiology Related to the Evaluation of the Working Capacity of the Physically Impaired. *Occup. M.*, 1946, 1: 1.

This report is the third in a series devoted to the United States Civil Service Commission's program for the employment of physically impaired persons.

Examination of a human being to find what work he is fit for involves knowledge of a method not yet possessed by medical science, namely, a method of estimating reserve compensation. Present techniques of measuring job requirements and physical capacities are only reasonable guides. They have value only as guides since there is a substantial margin of error both in the determination of the requirements of the job and in the physical evaluation and selective placement of the applicant. In the final analysis, regardless of what systems of job analysis and of evaluation of working capacity are used, the two most important factors in estimating physical capacity for work are the diagnostic acumen of the examining physician and his knowledge of industrial conditions.

In this connection, the future of the physically impaired in government or private industry will be as good as the type of preventive industrial medical service which management is willing to provide. The future of industrial medicine is closely allied to "human engineering" in the promotion of individual physical and mental hygiene, nutritional guidance, physical training, and the control of fatigue, as well as in the aiding of management in the selection of employees for specific types of work. In this connection, periodic re-examination of employees and jobs probably should be mandatory, especially in the case of the physically impaired.

The "must" in dealing with the applicant for work who presents an impairment, whether he is a veteran or a nonveteran, is to give him a fair chance to make good under his own power plus whatever assistance or special benefits are provided by law—state, municipal, or federal.

The general risk that an employer takes in hiring seemingly normal persons without being able to measure the large number of success factors involved in work is considerable. It may exceed any risk he takes with physically impaired persons whose capacities have been evaluated and matched with the requirements of the job. Mistakes in placing the worker with an impairment are inevitable, as in the case of the able bodied, but the failure of a person with a particular type of defect to do a particular job should not prejudice an employer against considering another person with the same defect for the same job

unless it has been definitely substantiated that there is a physiologic or a psychologic contraindication in the requirements of the job. In cases in which there is a doubt whether the remaining capacities of the person with an impaired function are adequate for successful performance of the job, the doubt should be resolved in favor of the applicant, with the understanding that if he does not prove successful in the job, he may be referred to appropriate rehabilitation authorities or reassigned, and that if this is not possible, his employment may be terminated.

WALTER H. NADLER, M.D.

Loehle, J. F.: Oral Plasma Feeding. *J. Pediat.*, S. Louis, 1946, 28: 145.

Many investigators have advised the incorporation of proteins, in some form or other, in neonatal and complementary feedings as the best method to remedy neonatal weight loss. Human milk is not Nature's first food substance of predilection for the human newborn infant, for the human breasts first and foremost provide colostrum. The closest available substance corresponding to colostrum is human plasma, provided the fat content be removed.

With these facts in mind, 7 premature infants were fed orally with a plasma solution in place of any other nutrient substance, and after 24 hours of this type of feeding, plasma was added to the variously constituted neonatal feedings. The object was to reduce the limitations set by employing merely one or two types of neonatal feedings.

In all cases neonatal weight loss ceased, and the infants thrived. Moreover, all of them showed appreciable weight losses when the plasma was subtracted from the feedings. These changes were more conspicuous than those observed in other types of neonatal feedings of high protein content. Intestinal disturbance was absent if the plasma when fed to the infants was free of red cells and suspicious antigens.

ERNEST E. ARNHEIM, M.D.

Slobody, L. B., Benson, R. A., and Mestern, J.: The Induction of Vitamin C Subnutrition. *J. Pediat.*, S. Louis, 1946, 28: 134.

Sixteen children ranging in age from 5 to 11 years were given from 50 to 300 mgm. of ascorbic acid daily until the skin test (based on the intradermal injection of a dye which is decolorized by Vitamin C) and the plasma ascorbic acid levels were within normal range (more than 0.2 mgm. per cent). This was usually accomplished in from 1 to 3 weeks. Then the diet, which contained no citrus fruits or tomatoes, was begun. Before the diet was started, the skin test time was 9 minutes or less in 14 children and 11 minutes in 2 children. The ascorbic acid levels in the blood ranged from approximately 0.5 to 1.9 mgm. During the diet, the skin test time became prolonged beyond 14 minutes in all of the

children. The skin test time was again shortened to normal following the administration of from 25 to 200 mgm. of ascorbic acid per day. During the diet most of the plasma levels of ascorbic acid fell. The blood levels rose following the administration of ascorbic acid.

The children felt well during the entire study and there were no abnormal physical findings. The blood counts and roentgenograms were essentially normal. In 5 cases the serum phosphatase was found to be within normal limits. Gross and some biomicroscopic examinations of the gums revealed some gingival manifestations of vitamin C deficiency, but no attempt was made to evaluate and correlate these findings.

ERNEST E. ARNHEIM, M.D.

Karelin, V. M., and Tscharnaya, D. S.: The Treatment of Internal Hemorrhages and Hemorrhagic Diatheses with Vitamin K. *Vrachebuoe Delo*, 1945, p. 11.

Palladin prepared a water soluble vitamin K, which is the sodium salt of methyl-naphthohydroquinone-sulfo acid and is only half as toxic as the alcoholic solution of vitamin K₃ or methyl-naphthoquinone.

The authors were able to increase the coagulability of the blood and to diminish the bleeding time in nearly all of their patients by administering one or the other of these mentioned products. Vitamin K was used in the form of an alcoholic or aqueous solution and also in the form of tablets. The drug was administered 2 or 3 times a day for 3 days in succession, each individual dose containing 10 mgm. of the active substance. If the bleeding did not stop after 3 days the treatment was continued for 3 days more.

Vitamin K₃ was found to be very effective in the treatment of pulmonary, gastric, and uterine hemorrhages. In patients with hemophilia the blood began to coagulate earlier than in the control experiments. In icteric patients the administration of vitamin K₃ was followed by a diminution of the amount of bilirubin in the blood. This observation suggests an improvement of the liver function. In patients with gastric hemorrhages, blood disappeared from the feces after the administration of vitamin K₃. In 1 patient with a cancer of the stomach the blood in the feces persisted but the number of thrombocytes rose from 84,000 to 200,000. In patients with Werlhoff's disease, epistaxis and subcutaneous hemorrhages ceased after the administration of vitamin K₃. In all instances the amount of prothrombin increased.

The authors conclude that vitamin K₃ deserves greater use for prophylactic treatment and is also indicated in the therapy of pulmonary, gastric, and uterine hemorrhages.

JOSEPH K. NARAY, M.D.

Van Vyne, A.: Prothrombinemia in Hemorrhagic Diatheses and Its Response to Vitamin K. *Rev. belge sc. med.*, 1944, 15: 173.

The different methods of determining the prothrombin level of the blood are discussed. The

author prefers the two stage method of Smith, Warner, and Brinkhous which permits a true titration of the prothrombin. Thromboplastin and calcium are added to the defibrinized plasma, which transforms the prothrombin into thrombin. To this mixture fibrinogen is added and the coagulation time taken with increasing dilutions of plasma. The highest dilution which shows coagulation within 15 seconds indicates the prothrombin level.

Large series of tests were done in human beings and animals (dog, rabbit, and chicken). The most significant results were:

1. In normal persons, the prothrombin level is very constant and hardly varies in the same individual. The same holds true for dogs. All values below 80 per cent are to be considered pathological. Hypoprothrombinemia has never been observed as a spontaneous occurrence, but may be produced experimentally by the injection of vitamin K; it is transient and followed by a short period of hypoprothrombinemia.

2. The role of the liver is a double one: (a) resorption and storage of vitamin K of exogenous or endogenous origin (therefore, a considerable decrease of the prothrombin level in biliary obstruction can be corrected promptly by vitamin K treatment) and (b) under the influence of vitamin K, the liver produces the necessary amount of prothrombin. Any damage of the liver causes hypoprothrombinemia. This responds more or less favorably to the administration of vitamin K, according to the functional condition of the liver. Thus, the response to vitamin K can serve as a test to the extent of liver damage. This was shown in cases of portal cirrhosis, icterus catarrhalis, acute hepatitis, and carcinoma. The success of blood transfusions in hemorrhagic diathesis of hepatic origin is based only on the prothrombin content of the transfused blood.

3. In anaphylactoid purpura (Henoch, Schoenlein) and in peptone shock of the dog, sudden hypoprothrombinemia occurs; this responds to vitamin K and seems to indicate a relationship between liver damage and anaphylactoid purpura.

4. The normal newborn shows a marked hypoprothrombinemia of from 25 to 30 per cent; premature infants present even less.

5. Other pathological conditions, like pernicious anemia and severe malnutrition, also reveal marked hypoprothrombinemia.

WEENER M. SOLMITZ, M.D.

Robinson, D. T., McLeod, J. W., and Downie, A. W.: Dust in Surgical Theaters as a Possible Source of Postoperative Tetanus. *Lancet*, Lond., 1946, 1: 152.

Tetanus following surgical operations is relatively rare, although in civilian practice almost 10 per cent of more than 3,000 cases of tetanus reviewed by Wainwright in 1926 were postoperative. It is usually impossible to prove the source of infection in these cases, although various materials have been incriminated on circumstantial evidence. Catgut has

often been blamed, and occasionally the evidence for this has been strong (Mackie, 1928). Imperfectly sterilized dressings and instruments, the skin at the operation site, and sulfonamide powders have also come under suspicion. Toxigenic tetanus bacilli have been found in human feces by various observers, although the incidence of this apparently varies in different countries and different communities, and the intestinal tract of the patient has therefore been regarded as the source of infection in abdominal or gynecological operations (Tulloch, 1919).

Tetanus bacilli are often present in soil and street dust from which wounds due to accidents may become infected. Dust in hospital wards or operating theaters has not often been seriously considered as a possible source of tetanus infection of operation wounds, but the observations made in relation to the 2 cases reported indicate that this possible source should not be overlooked.

Steps should be taken to exclude as far as possible infected dust from operating theaters. This would involve, among other measures, the wet dusting of operating theater floors and walls with antiseptic solutions, the filtering of the air coming into the theater through ventilating shafts, and precautions against the introduction of infected dust on the footwear of theater personnel. This last measure might be effected by insisting that at some point in the corridor sufficiently remote from the theater everyone entering should put on gumboots or some equivalent which had been left standing in a potent antiseptic solution. JOHN E. KIRKPATRICK, M.D.

Bachman, A. L., and Bershon, A. L.: The Roentgenographic Appearance of Temporomandibular Hydrarthrosis. *Radiology*, 1946, 46: 251.

The roentgenographic diagnosis of effusion into the temporomandibular joint has only rarely been reported. A comprehensive review of the literature revealed a single case record.

Effusion into the temporomandibular joint has been reported as occurring in a variety of conditions. These have been grouped as (a) traumatic arthritis, (b) rheumatoid arthritis, and (c) suppurative pyogenic arthritis.

While effusions in the temporomandibular joint have been noted as occurring in such conditions, a careful search through the literature revealed no reports other than the report of Bishop, in which the diagnosis of hydrarthrosis was made by x-rays.

A considerable similarity of symptoms exists in cases of acute hydrarthrosis and of dislocation of the temporomandibular joint. There is severe pain and tenderness in the temporomandibular region associated with marked limitation of mandibular movement in both. Roentgenographic examination appears of major importance in the differentiation between effusion and condylar luxation. The necessity for excellent roentgen demonstration of the joint in several views is therefore apparent.

The diagnosis of temporomandibular joint effusion led to conservative treatment with heat and rest, as

Fig. 1. Appearance of patient on admission. Note protrusion of the lower jaw forward and to the left.

in any other acute hydrarthrosis. The rapid recovery observed clinically and roentgenographically was strong evidence in substantiation of the diagnosis.

The cause of the effusion in this patient was uncertain. Two possibilities appear most worthy of consideration, the others being more or less excluded by the short course of the illness. Although the patient gave no history of any excessive movement of the jaw, the possibility exists that he may have unconsciously moved his mandible into an abnormal position during sleep. The second possibility is that the hydrarthrosis was an early manifestation of rheumatoid arthritis and that other joints may become involved at a later date.

HARRY W. FINK, M.D.

DUCTLESS GLANDS

Albert, A.: The Experimental Production of Exophthalmos in the Fundulus by Means of Anterior Pituitary Extracts. *Endocrinology*, 1945, 37: 389.

Experimental hyperthyroidism has been produced in many animals by the injection of hypophyseal extracts. Hyperthyroidism with exophthalmos could be produced in ducks, guinea pigs, and also in the fundulus, the common Atlantic "minnow."

Healthy specimens of fundulus heteroclitus, Linn., measuring from 3 to 4 inches in length were kept in a stock tank of running tap water. Impure preparations of both follicle stimulating hormone

Fig. 1. Two exophthalmic fish (left and right) 12 hours after a single injection of sheep anterior pituitary extract. Normal fish in the center for comparison.

(F.S.H.) and the luteinizing hormone (L.H.), obtained from whole pituitary glands of sheep, were injected through the cloaca into the peritoneal cavity. As early as 3 hours after a single injection, exophthalmos was noticed with a maximum demonstration on the second or third day after a single injection. The exophthalmos lasted about 2 weeks and the eye balls then reverted to normal.

Protein from other sources did not produce exophthalmos, nor did other hormonal substances including thyroid and thyroxine. Exophthalmos was produced only by a pyridine extract of sheep pituitary, by the F.S.H., L.H., and thyrotropic hormones. A rapid method of preparing the exophthalmic factor (E.F.) was devised by precipitation with ammonium sulfate, and following dialyzation and centrifuging. The resulting clear solution contained 2 gm. eq. per cubic centimeter, or about 40 E.F. units per cubic centimeter.

Relation of the thyroid to exophthalmos. Although it was shown that thyroid hormone did not produce exophthalmic reaction, it was of interest to determine if any changes occurred in the thyroid during exophthalmos production. Although exophthalmos was definite at 3 hours after injection, no changes in the thyroid were noticed at that time. Six hours following the injection, increased vascularity of the thyroid was noticed. Twenty-four hours after the

injection, reduction and vacuolization of the cells was noticed, vascularity was maximal, the follicular cells were taller, and the nucleus was found to be closer to the base.

The mechanism of exophthalmos. On histological examination, a large triangular shaped edematous mass containing a few leucocytes and lymphocytes, was found within the retrobulbar space. An increased amount of free fluid could be aspirated by puncture of the conjunctiva, following which the proptosis disappeared. The amount of this aspirated fluid was 0.05 c.c. as compared with 0.01 c.c. obtainable from the normal fundulus, and the fluid was under pressure.

If a drain was inserted into the retrobulbar space of one eye, or the dorsal half of the conjunctiva was slit so that fluid could escape, no exophthalmos developed after the injection of E.F. in this eye, while the other eye showed exophthalmos. The injection of saline solution directly into the retrobulbar space produced only transitory exophthalmos, for about 18 hours, which indicated that the orbital tissues could absorb artificially instilled retrobulbar fluid. However, if pituitary extract was injected the exophthalmos might last for more than a week, which showed a direct action on the orbital tissue. The production of exophthalmos by pituitary extract was not affected by section of the sympathetic chain, by anesthesia, or by hypophysectomy.

It is assumed that in the fundulus the pituitary principle acts directly on the orbital tissue, causing edema and cellular infiltrations of the areolar and fat tissue, as well as of the muscles and conjunctiva, and forming free retrobulbar fluid. The accumulation of fluid exerts pressure on the posterior surface of the eyeball which thrusts it out of the orbit as soon as the pressure overcomes the inward pull of the extraocular muscles. Remission of the exophthalmos in the fundulus is believed to be due to absorption of the fluid.

UNUSUAL METASTATIC MANIFESTATIONS OF BREAST CARCINOMA

I. Metastasis to the Mandible with a Report of Five Cases

FRANK E. ADAIR, M.D., F.A.C.S., and JULIAN B. HERRMANN, M.D., New York, New York

PERTHES in 1907 wrote, "the rarest form of jaw carcinoma is the metastatic." Almost 40 years have elapsed since this observation was recorded, yet its validity has remained unchallenged. During this period roentgenology, the greatest aid in the diagnosis of osseous metastases, had its origin and development. Evidently the paucity of reported instances of metastatic involvement of the mandible cannot be ascribed to the inadequacy of diagnostic facilities during these years. As recently as 1936, Geschickter stated that "although carcinoma metastasizing to bone is a relatively common condition, the upper and lower jaw are rarely involved." It is conceivable that a metastatic focus in the mandible might remain asymptomatic and thus be overlooked, but such instances must be extremely infrequent.

Three lesions which frequently produce osseous metastases are carcinoma of the thyroid, prostate, and breast. Metastasis to the mandible from these primary sites, however, appears to be uncommon in thyroid carcinoma and extremely infrequent in breast and prostatic cancer. Rare examples of metastasis to the mandible from carcinoma of the lung, rectum and kidney have been reported (Stern and Shepard, Blum). Some authors (Ehrhardt, Blumer) have described a number of cases of

metastasis of thyroid carcinoma to the mandible, but we have been able to find only 11 recorded instances of metastatic involvement of the mandible from carcinoma of the breast. To this number we add 3 of our own.

The earliest recorded case is that of Batzaroff who in 1829 described the occurrence of metastasis to the mandible 21 months after a mastectomy for mammary carcinoma. There was no evidence of local recurrence. There is no other reported example until 1909 when Schlesinger published reports of 5 cases of lower jaw metastatic lesions, 4 associated with carcinoma of the breast, and 1 with carcinoma of the prostate. About 20 years later, Blair, Brown, and Womack wrote that they had noted metastatic carcinoma of the jaw three times, once from the rectum and twice from the breast. No details were given.

In 1930 Sonntag described the case of a 65 year old woman who consulted him because of a swelling of the left lower jaw of several months' duration. She had undergone a left radical mastectomy 3 years previously. There was no evidence of metastasis elsewhere, therefore the mass in the mandible was considered a primary tumor and the jaw was resected. Microscopic examination revealed the jaw lesion to be metastatic mammary cancer. The patient died one year later. Skillen also in 1930 reported the case of a 40 year old

From the Breast Service of the Memorial Hospital, New York.

woman with a metastatic lesion to the mandible, proved histologically, from a breast carcinoma.

The same year (1930) Thoma, in his textbook gave an abstract of 2 cases. One, a 46 year old woman, developed a metastatic lesion in the left mandible following a mastectomy for colloid carcinoma of the left breast. The second patient developed a metastasis to the left mandible from an adenocarcinoma of the left breast. It is of interest that Rogers and Flo have reported a case of metastasis to the mandible consequent upon a breast fibrosarcoma.

The most recent example published is by Burket in 1941. This was a 38 year old woman who developed metastatic disease in the right mandible 4 years after a left radical mastectomy for carcinoma.

Our 5 cases are as follows.

CASE 1. B.E., a 41 year old female, underwent pre-operative irradiation and a right radical mastectomy 3 years before coming to the clinic. The pathological diagnosis was adenocarcinoma grade 3 with node metastasis. One year following the mastectomy the patient had an extraction of a left lower molar with subsequent numbness of the lower left side of the face and swelling of the left mandible. These symptoms persisted. Her chief complaints on admission were cough, dyspnea, pain in the chest and back, anorexia and occasional vomiting, and swelling of the left mandible.

Examination revealed a well healed right radical mastectomy scar. There was no evidence of local recurrence and no adenopathy. In the horizontal ramus of the left mandible near the junction of the middle and posterior thirds there was a smooth, hard, fixed, painless, nonulcerated mass about 2 centimeters in diameter, involving the whole thickness of the bone.

Roentgen studies disclosed evidence of metastasis to the pelvis and extensive destruction of the horizontal ramus of the left mandible (Fig. 1). An aspiration biopsy of the mass on the mandible was reported as metastatic carcinoma consistent with mammary origin. The patient was given a small amount of roentgen therapy to mandible but died of metastases about 4 months after her initial visit.

CASE 2. J.C., a 63 year old woman, consulted the clinic because of a lump of 18 months' duration in the right breast. The lump had been growing slowly until 2 months previously when it began to ulcerate. Examination revealed the right nipple and areola to be completely replaced by a hornifying crust and the central portion of the breast to be entirely filled by a stony hard tumor mass 6 centimeters in diameter. There was no palpable adenopathy.

The patient refused operative therapy and failed to return to the clinic for 2 years. Despite the elapsed time the condition was still operable although nodes were now palpable in the right axilla. A radical mastectomy was performed following which she made a good recovery. An area on the anterior right chest wall required a skin graft.

The pathological report on the surgical specimen was infiltrating duct carcinoma grade 3, with metastasis to the axillary lymph nodes. Because the grafted area was slow to heal the patient did not receive any postoperative x-ray therapy.

Her return visits to the clinic were irregular at first and then ceased for about 9 months. She then consulted the clinic because of the appearance of some nodules in the skin of the right chest wall at the edge of the previous graft. A biopsy of one of these nodules was reported as recurrent carcinoma and radiation therapy was advised. She failed to return for 8 months at which time low voltage irradiation was administered to the right anterior chest wall.

Another 4 months' period of absenteeism from the clinic followed. At the end of this interval the patient returned because of an enlargement in the right mandible and right temporal region. Examination revealed a hard swelling involving the right mandible. A roentgenogram disclosed numerous and extensive areas of bone destruction in the right mandible and skull which were interpreted as carcinoma metastases (Fig. 2). She received a small amount of x-ray therapy in the right side of the face but failed to return for further treatment and was lost to follow-up.

CASE 3. M.R., a 43 year old woman, underwent a radical mastectomy for carcinoma of the left breast in January, 1940. The pathological diagnosis was infiltrating duct carcinoma grade 3 with metastasis to multiple axillary nodes.

The patient remained free from apparent disease for about 2½ years. Then she developed a mass over the left third rib about 2 centimeters from the lateral border of the sternum. A roentgenogram disclosed an area of destruction in the anterior part of the third left rib. There was no other evidence of disease.

In view of the desperate situation the involved area of the rib was resected and at the same time the patient was sterilized, a panhysterectomy being performed. The pathological report on the excised tumor of the rib was "mammary carcinoma invading rib."

For about 1 year following this she was apparently free of disease. A roentgenogram of the chest at the end of this period failed to reveal any evidence of disease. A short time later, however, the patient developed paresthesia ("sensation of pins and needles") in the left side of her face. She considered the condition a neuralgia and treated herself. The paresthesia changed in character and became a sensation of numbness over the left lower jaw.

Several months later the patient developed pain in the lower dorsal region and a lump in the left lower

Fig. 1. Roentgenogram, Case 1, showing extensive destruction of the horizontal ramus of the left mandible.

Fig. 2. Case 2. Numerous and extensive areas of bone destruction in right mandible and skull are shown.

jaw. The sensation of numbness over the left mandible still persisted. An x-ray examination of the lumbar spine and pelvis revealed numerous areas of metastasis. Roentgenographic study of the mandible disclosed an area of destruction in the horizontal ramus (Fig. 3). There were also at this time metastatic deposits in the scalp and in the skin of the chest wall. She received x-ray therapy to all of the metastatic lesions and is still living with active disease 5 years after her radical mastectomy.

CASE 4. E.M. was a 51 year old woman who in 1936 underwent a simple mastectomy for carcinoma of the left breast at another institution. She was apparently free of disease for about 2 years. Then a swelling appeared over the angle of the right mandible for which she consulted this clinic. Roentgeno-

graphic studies revealed a large area of bone destruction in the ascending ramus of the right mandible (Fig. 4). The roentgenologist believed that it presented more of the features of a primary bone tumor such as an adamantinoma rather than those of metastatic carcinoma. The irregularities of bone destruction, and the somewhat honeycomb appearance, made a diagnosis of a primary bone tumor such as an adamantinoma seem more likely. Films of the chest failed to reveal evidence of a primary tumor or metastases. Roentgenograms of the pelvis, spine, legs and arms exhibited no evidence of bone destruction or carcinoma metastasis.

An aspiration biopsy of the mass in the mandible was performed and reported as adenocarcinoma consistent with mammary origin. A submitted slide of

Fig. 3. Case 3. An area of destruction in horizontal ramus is shown.

Fig. 4. Case 4. Roentgenogram reveals a large area of bone destruction in ascending ramus of the right mandible.

Fig. 5. Case 4. Four months later roentgenogram reveals considerable bone regeneration in the area of destruction about the angle of the mandible

the original breast tumor was reported as infiltrating duct carcinoma grade 3, and this material was considered by Dr. Fred Stewart as perfectly consistent with that obtained from the mandible by aspiration.

The patient received x-ray therapy to the metastatic lesion in the mandible with considerable regression of the mass. A roentgenogram taken 4 months later revealed evidence of considerable bone regeneration in the area of destruction about the angle of the mandible (Fig. 5). Physical examination 2 years after this film was made revealed the right mandible to be slightly larger than the left near the angle.

Soon after this the patient developed anorexia, flatulence, and generalized abdominal pain. On examination a mass was found in the epigastrium. There was no other demonstrable evidence of disease. The patient's condition gradually deteriorated and she died in 1942, 6 years after the removal of the breast for carcinoma. An autopsy revealed metastatic adenocarcinoma in the liver, mediastinal, and peripancreatic lymph nodes. The metastatic cancer was reported as consistent with a mammary origin.

CASE 5. M.P., a 50 year old woman, consulted the clinic in June, 1943, because of a lump in the left breast of 3 years' duration and because of irregular menstrual periods of 9 months' duration. Examination revealed the right breast to be elevated, the nipple retracted, and ulceration at the junction of the nipple with the areola. Beneath the areola was a hard, nodular 2 by 3 centimeter mass attached to the overlying skin. A hard mass was palpable in the right axilla. Pelvic examination disclosed a mass posterior to the cervix which was thought to be an ovarian tumor.

An aspiration biopsy of the breast mass revealed carcinoma; therefore a radical mastectomy was performed. The pathological diagnosis was infiltrating

duct carcinoma grade 3 metastatic to the axillary lymph nodes at all levels. She received a cycle of postoperative x-ray therapy.

Upon the completion of the x-ray therapy a diagnostic curettage was done. The pathological report was adenoma malignum grade 2. The patient then received intrauterine radium therapy. Later a supracervical hysterectomy and bilateral oophorectomy were performed. The pathological report was corpus adenocarcinoma grade 2 and malignant endosalpingioma of the left ovary.

Following all of these procedures the patient remained in apparent good health for about a year. Then she began to have pain in the lumbar spine which upon roentgenographic studies was found to be in consequence of metastasis to the lumbar spine and pelvis. She received high voltage irradiation to these areas with amelioration of her pain.

About 5 months later she began to complain of pain in the knees. X-ray studies disclosed changes in the tibiae and lower left femur which were thought to resemble Paget's disease. For confirmatory evidence an x-ray plate of the skull was taken which revealed evidence of the presence of extensive diffuse destruction. This was interpreted as carcinoma metastasis. Blood chemical studies gave results which were consistent with bone metastasis but not with Paget's disease. The patient received x-ray therapy to the knees with subsidence of the pain.

Three months after this episode she began to experience pain in the right mandible. Examination of this area disclosed a small, swollen, tender area over the horizontal ramus. A roentgenogram of the right mandible revealed a large irregular area of bone destruction in the anterior half of the horizontal ramus (Fig. 6). The mandible was irradiated and the pain subsided.

Fig. 6. Case 5. Roentgenogram reveals a large irregular area of bone destruction in the anterior half of the horizontal ramus of the right mandible

The lesion in the mandible could have been metastatic from any of the 3 primary lesions but on the basis of probability it most likely was secondary to that in the breast.

The first indication of metastatic disease of the mandible may be pain, frequently in association with a loose tooth. In these instances the patient is usually seen first by the dentist and the tooth extracted as in the case reported by Burket and in our own Case 1. It is only later that the underlying cause is recognized. Paresthesia on occasion may be an early sign of metastatic invasion of the mandible. This is exemplified by our Cases 1 and 3. Pressure on, or involvement of, the mandibular nerve by the disease produces pain or numbness which stops sharply at the mid-point of the symphysis menti.

In some instances paresthesia of the side of the face and of the buccal and gingival mucous membrane may persist for a long period of time without any evidence of involvement of the mandible. This phenomenon is illustrated by the following case.

E.F. was a 43 year old woman who underwent a right radical mastectomy followed by x-ray therapy for carcinoma 3 years before consulting this clinic. Examination revealed no evidence of disease. During the ensuing 18 months she developed metastatic nodules in the right chest wall and nodes in the left axilla. About the end of this period she began to experience a sensation of numbness in the skin of the lower right face over the mandible and in the corresponding buccal and gingival mucous membranes. This area of paresthesia was sharply delimited at its medial aspect by the symphysis menti. Roentgenographic studies of the skull, mandible, lumbar spine, pelvis, and chest failed to reveal any evidence of metastasis. Six months later the paresthesia was unchanged and repeat x-ray studies of the skull and mandible failed to reveal any changes. The patient lived 7 months longer and during this period the paresthesia persisted without any external evidence of mandibular involvement.

In some instances in which a single metastasis localizes in the mandible a number of years after a mastectomy for carcinoma, the true nature of the condition may be overlooked and a diagnosis made of primary mandibular neoplasm. This happened in Sonntag's patient, and the mandible was resected. In our Case 4 a primary malignant lesion of the mandible was suspected. There were no other foci of disease and the roentgenographic

appearance was suggestive of a primary neoplasm. This would indicate that the roentgenogram may not always solve this type of diagnostic problem. In this connection New and Figi state that it is impossible to distinguish roentgenologically many of the primary tumors of the jaw from the metastatic malignant tumors. In some instances, however, aspiration biopsy may be of value, as in our Cases 1 and 4. By this procedure it may be possible to spare the patient a useless operation.

An interesting and perplexing problem is presented as a consequence of the finding that carcinoma of the breast manifests a predilection for certain osseous metastatic sites whereas other localities are relatively immune. Paget about 50 years ago commented on this saying "The evidence seems to me irresistible that in cancer of the breast the bones suffer in a special way which cannot be explained by the theory of embolism alone. Some bones suffer more than others; the disease has its seats of election." The theories of metastatic spread attempt to explain this phenomenon. A few of the more important theories will be briefly reviewed in an endeavor to elucidate an explanation for the infrequent involvement of the mandible.

Von Recklinghausen in 1891 was one of the first to suggest that malignant tumors metastasize to bone by means of the blood stream. According to this theory the tumor emboli become lodged in the marrow and develop a metastatic focus. His conclusion was based on the following observations: (1) Osseous metastatic lesions occur in the medullary cavity and reach the periosteum by direct extension. (2) If there is subperiosteal involvement it is always in the region of the large foramina which serve as an exit for the veins. (3) The cancer cells are found in definite channels within the marrow which he believed to be venous rather than lymphatic. It is suggestive that in 4 of the present series the lesion appeared in the horizontal ramus and in the fifth, the angle of the mandible was involved. This might be explained on the basis that hematogenous cancer emboli enter the medullary cavity through the mandibular foramen.

Handley advanced the theory that cancer is disseminated to bone by permeation through

the lymphatics. He believed that the bones nearest the breast, namely, the ribs and sternum were involved by direct extension but that the more distant ones were invaded by permeation of the cancer cells through the deep fascial lymphatics. Invasion of the bones took place at those points where they approached the skin and were consequently nearest the deep fascia. In the femur this was at the site of the great trochanter and in the humerus at the site of the deltoid insertion.

He explained the rarity of metastases to the forearm, hand, leg, and foot on the basis that lymphatic permeation was in general a slow process and that the patient died before it extended as far as the bones of the extremities. This explanation does not account for the infrequency of metastatic involvement of the mandible because the skull, which is further distant from the primary lesion than the mandible, is not infrequently the site of metastatic disease.

Carnett and Howell, while agreeing in essence with Handley's theory have advanced some important modifications. They believe that the humerus is invaded in most instances by direct permeation of the disease from the axillary lymph nodes which have become cancerous by lymphatic emboli rather than by permeation along the deep fascia of the chest wall. According to their conception the metastases localize initially in the head of the humerus and glenoid process of the scapula rather than at the deltoid insertion as suggested by Handley. The cervical vertebrae and skull are involved by a process of permeation and embolism extending from the axillary lymphatics along the infraclavicular and supraclavicular lymphatics beneath the deep fascia. The lumbar vertebrae and pelvis are involved by direct extension from the retroperitoneal lymph nodes which have become cancerous by permeation from the breast along the periaortic lymphatics. The invasion of the femur is by direct extension to the femoral head from the pelvis through the lymphatics of the ligamentum teres.

In recent years Batson has demonstrated that it is possible for material injected into the peripheral venous circulation to reach the

spine, pelvis, and skull by way of the vertebral veins without passing through the lungs. This may be the pathway in some instances of metastatic spread.

It is well established that the skull is a common site of metastasis in breast carcinoma. Carnett and Howell in their series of 101 cases of osseous metastasis from breast carcinoma found the skull involved in 14 cases but mentioned no instance of mandibular involvement. Lenz and Fried in an analysis of 81 cases encountered skull involvement in 33 per cent and no instance of mandibular disease. If involvement of contiguous bones is by direct spread, as Carnett and Howell maintain, citing as an example invasion of the head of the femur from disease of the pelvis, then the mandible ought to be involved more frequently by direct extension from the skull. Furthermore if involvement of the mandible is by direct spread from the skull it would be logical to expect the region of the condyles to be invaded early. It appears, however, that when metastatic invasion of the mandible does occur it may be in the horizontal rather than in the ascending ramus. This was demonstrated by 4 of our cases.

An interesting theory has been suggested by Pinney. He believes that bone metastases are produced by blood borne emboli which lodge in the thin walled blood channels of the red marrow, and he has been able to demonstrate plugs of epithelial cells in this location. He was unable to demonstrate any lymphatics in bone marrow and concluded that they are absent. He postulates that not only must the cancer emboli reach the marrow but the current here must be slow enough to allow the cells to lodge and grow. These conditions are satisfied by the red marrow which, because of its great vascularity, produces a widening of the blood stream bed with a consequent slowing of the current.

The localization of bone metastases is explained by this theory on the basis of red bone marrow distribution. In the infant all the bones contain red marrow but by the time adult life has been reached this has been replaced by fat except in the skull, sternum, ribs, clavicles, scapulae, vertebrae, os innominatum, and the proximal portions of the ex-

tremities where red marrow continues to persist throughout life (Doan).

Pinney ascribes the infrequency of metastasis below the elbow and knee to the absence of red marrow in these locations. He believes that bone metastasis may occur occasionally by way of the lymphatics but that the principal route is hematogenous. It is probable that both lymphogenous and hematogenous routes are essential to bone metastasis.

Some investigative work carried out by Box is of interest in this connection. He examined numerous areas of a series of human jaws and in 75 per cent found only yellow marrow. In the remainder there were small, discrete areas of red marrow encountered. From his researches he concluded that even in early adult life the bone marrow in the average normal jaw is of the fatty or yellowish variety. In those instances in which small patches of red marrow were found he believed it was due to: (1) vestiges of original red marrow that had not undergone change; (2) local stimuli such as trauma from a tooth extraction, root canal filling, or gingival infection.

This infrequency of the presence of red marrow in the mandible might, on the basis of Pinney's theory, account for the rarity of metastasis to the mandible in breast carcinoma. The only contradictory evidence is furnished by Ehrhardt's report of 65 cases of malignant struma with bone metastases, 30 of which were to the mandible. This percentage is so high that it suggests the possibility that many of these were due to direct extension rather than metastasis.

SUMMARY

1. Eleven examples of metastasis to the mandible from breast carcinoma were found reported in the literature.

2. Five cases observed in this clinic are presented.

3. Various theories of metastatic spread are briefly reviewed in an attempt to explain the apparent immunity of the mandible to metastasis.

4. The explanation is advanced that the mandible is infrequently involved by metastatic disease because of the customary absence of red marrow.

THE PELVIC FLOOR IN PARTURITION

RICHARD M. H. POWER, M.Sc., M.D., C.M., F.A.C.S., Montreal, Canada

THE orderly sequence of changes in the structure of the pelvic floor during parturition has received little or inadequate attention in recent publications. A consecutive account of what happens in the constituent structures of the floor during parturition seems opportune. While textbooks are spotty in their description of the structural anatomy, there is a manifest lack of consecutive description in the anatomical sequence of events, and particularly of the admirable structural adaptations for this natural event.

The enquiring senior students, after study and mature reflection, frequently ask: What happens to the much heralded fascial structures during delivery? How does the levator ani muscular diaphragm dilate? What becomes of the double leafed fascial structure, the urogenital diaphragm? How does it open up when the fetal head passes through it?

Briefly, at the moment of expulsion of the fetal head, the pelvic floor and the urogenital tract are converted into one continuous cleft (Figs. 1, 2, 14). At this moment, the lateral ligaments of the cervix uteri (Mackenrodt) are flattened in transverse, and elongated in vertical, section. The levator ani muscular diaphragm is funnelled. The urogenital diaphragm, or as it is more popularly known, "the triangular ligament," is opened up and closes again (Figs. 1 to 3, 5, 6, 10, 13 to 15). The smooth muscle diaphragm in the base of the broad ligament and the sphincteric group of muscles at the vulval outlet are dilated spherically. The latter are converted into a short muscular tube with the passage of the fetal ovoid.

Before these questions are answered in detail, and in order to avoid speculation, a brief anatomical preview of the pelvic floor is necessary.

From the Department of Anatomy, McGill University, and the Departments of Gynecology and Obstetrics, St. Mary's Hospital, Montreal. This work was partially assisted by a grant from the Cooper Fund of McGill University.

The pelvic floor is a musculofascial diaphragm. Extending into it posteriorly is a movable bony platform, the coccyx.

This musculofascial diaphragm is a composite structure of connective tissue, voluntary and smooth muscle and elastic tissue, arranged in five diaphragmatic layers, superimposed and interwoven one upon the other for reciprocal support. Neither singly nor united do these diaphragms form a complete sling or hammock across the pelvic floor, as they are perforated centrally by three tubular structures, the urethra, the vagina, and the anal canal. These canals are arranged very much like tubes passing through the shutters of a venetian blind. Their tubular openings are closed by the sphincteric arrangement of these musculofascial floors.

These diaphragms not only close the tubular openings, but serve as essential supports to the pelvic viscera; the endopelvic fascial and levator ani muscular diaphragms being the most essential. All five diaphragms have an anchorage into the perineal body. They are set at different planes (Fig. 3) and are fixed at different levels to the bony canal, which latter resembles the "elbow of a stovepipe." They act as so many floors of support to the viscera—placed like shingles—one gliding over the other in fluid movement, arranged that they may be dilated to their capacity as they are in parturition during the conversion of the pelvic floor into one large hiatus previous to expulsion. Dilatation of these floors occurs from above downward, and restoration comes about in the reverse order following delivery, provided their anatomical integrity has been maintained.

Trauma from childbirth is the principal cause of injury to the pelvic floor. Other causes may be congenital weakness, involution and atrophy of fat in old age, neurogenic injury to the fourth sacral nerve (spina bifida).

Following injury to any single or complete set of "uterine supports," prolapse may re-

sult. This prolapse may be complete or incomplete, as cystocele, where the anterior segment is injured, or rectocele with injury to the posterior segment, or sacropubic hernia, i.e., procidentia uteri, where anterior lateral and posterior segments are injured.

From above downward in anatomical order these diaphragms are as follows: (1) the endopelvic fascial diaphragm or upper pelvic fascial floor, (2) the smooth muscle diaphragm in the base of the broad ligament, (3) the levator ani muscular diaphragm, (4) the urogenital diaphragm, and (5) the sphincteric group at the vulval outlet.

While these composite structures differ in their development and in their function, nevertheless, collectively they are unique in their synchronous uniformity in response to functional demands. Their collective structural arrangement allows for marked excursions of distention and contractility.

Connective tissue is primarily a supportive structure in character. Fascia, in itself, is not unusually found in regions subjected to intermittent and varying degrees of tension. Usually it is most developed where it can respond as a passive elastic agent which must not be extended beyond its quantum of elasticity. Smooth or striated muscle, however, having the property of maintaining "tension" or "tonus" can withstand tension or stretching, which could not be tolerated by mere fascia. If, however, owing to nutritional or mechanical factors, its power of maintaining a high tonus is lessened, then it is a much less efficient supporting structure than is fascia. Smooth muscle has the property of maintaining, within fairly narrow limits, the same tonic force irrespective of the degree of stretch to which it is subjected until the limit of its elasticity is reached. From then on it behaves as an inactive fascial tissue. These considerations, when applied to the arrangements of the above tissues, are of fundamental importance. Smooth muscle tissue is found precisely in those regions where it is necessary to permit considerable dilatation, contraction, or movement of organs, meanwhile maintaining some degree of control of the movements of these organs independently and in relation to each other.

Fig. 1. Schematic representation. a, left, Structures at rest; b, uterovaginal canal converted into urogenital hiatus.

It is obvious that it is necessary to have a mechanism to restore the normal state after a major dilatation, etc., of one or more of the organs. It is equally obvious that fascia would be ineffective in such contingencies.

Dilatation of the connective tissue diaphragm, to the extent of permitting the passage of the fetal head, demands a great stretching of this poorly contractile tissue, which of itself could not assume its original dimensions as it contains little, if any, elastic tissue. Hence Nature has interposed a smooth muscle diaphragm between the endopelvic fascia and the levator ani muscle. Loss of elastic recoil and diminished sphincteric action are supplied by the presence of interwoven elastic tissue and smooth muscle fibers. The return to the normal postpartum state is assisted by the closely associated smooth muscle diaphragm which has the power of great extensibility. The fibromuscular diaphragm is not necessarily injured in normal childbirth. Dilatation of the uterus and cervical canal will slacken the tautness of the fibromuscular diaphragm, while return to the normal size of this viscus will renew the tension of the musculo-fascial diaphragm. By shifting of tissues and interplay of structures, marked excursion of dilatation and return to normal measures can take place in these associated diaphragms. These structural features are of great impor-

tance in the struggle for adaptability of spatial relationships that prevail between mother and child during parturition.

THE ENDOPELVIC FASCIAL DIAPHRAGM OR UPPER PELVIC FLOOR

If we look at a human embryo at about the 25th day, we find that the lower end of the abdomen is filled with a loose connective tissue through which the hind gut is passing dorsally and the allantois ventrally, these two structures meeting caudally in the cloaca. The coelom or the body cavity extends caudally for a short distance between the rectum and the allantois in front. Between the lower ectoderm wall of the abdominal cavity and the coelom is the subperitoneal pelvic space. In the embryo, this subperitoneal pelvic space is loosely packed with "embryonal connective tissue" and surrounds the as yet undifferentiated viscera. It really represents the as yet unseparated somatopleure and splanchnopleure, the body cavity not having yet extended into this region to make a clear division between these two tissues. This tissue of course arises from the mesoderm and more especially from the mesenchyme of the middle germ layer.

In a 2 months' fetus (Fig. 4-31 mm. C.R.L.) a definite central condensation of mesoderm

spans the fetal pelvis transversely enmeshing the lower third of the descending müllerian ducts. Their caudal extremity is thereby pulled caudally and medially, thus helping in their junction. This transverse mesodermal condensation is known as the "transverse mesodermal bar" by Fraser. In transverse section it can be seen to fan out into anterior, lateral, and posterior segments. In frontal section, it sends a caudal prolongation dividing the allantois from the rectum; thus separating the cloaca into the urogenital sinus anteriorly and the rectum posteriorly. This descending fascial prolongation terminates in the perineal body. At this stage, it is known as the urorectal septum. The anterior coronal segment is the anlagen of the cervicovesical fascia; the lateral condensation, the lateral ligaments of the cervix uteri (Mackenrodt); the posterior projection, the uterosacral ligaments; the caudal projection the rectovaginal septum. Thus the "transverse mesodermal bar" is the anlagen of the upper pelvic fascial floor.

In an eight month fetus the lateral ligaments of the cervix uteri (Mackenrodt) fuse with, and cover, the perimesium of the levator ani muscle and attaches solidly to the lateral vaginal walls.

In an adult multipara the endopelvic fascia reaches its greatest functional development, spanning the pelvis like a hammock, trans-

versely from levator ani white line to levator ani white line, and anteroposteriorly from the symphysis pubis to the 2nd and 3rd sacral vertebrae, interrupted centrally by the urethra, cervix and vagina, and the rectum, the supravaginal cervix being the central pivotal attachment. A definite fascial fibrous capsule is present attached to the anterolateral and posterior supravaginal cervix (Fig. 5). This capsule is so arranged as to correspond to the functional demands of parturition and to the prerequisites of gynecology.

The physiological response to functional demands is greatest in parturition. Synchronously with the unfolding of the lower uterine segment a corresponding hypertrophy and hyperplasia of the endoplevic fascial structures takes place.

In the adult female topographically in coronal section the endopelvic fascia forms a diaphragm divided into anterior, lateral, and posterior segments. The anterior segment represents a platform situated beneath the bladder. Its fibers extend from the supravaginal fascial collar anteriorly to the symphysis pubis and to the anterior part of the levator ani white line. The lateral segment or condensation is known as the lateral ligament of the cervix uteri (Mackenrodt) and extends from the lateral margin of the supravaginal fascial collar to the levator ani white line. This is a well defined fascial ligamentous connective tissue capsule in the form of an inverted U (Fig. 6). It is attached to the anterior, superior, and posterior marginal walls of the supravaginal cervix. Laterally and inferiorly, this capsule is attached to the levator ani white line and to the levator ani fascia. It has anterior, superior, and posterior surfaces.

The superior surface presents large veins on its posterior aspect, while anteriorly the uterine artery is an individual entity, coursing above the fascial surface and marking the line of cleavage between this surface and the vesical fascia. Toward the lateral aspect, a reef of fascia extends obliquely from the posterior to the anterior leaf of the broad ligament above the capsule, deflecting the ureter in its lateral position.

At the extreme lateral aspect of this surface, the uterine artery crosses the ureter at a right

Fig. 3. Schematic representation of the various structures forming the pelvic floor. The lateral and posterior cervical ligaments L.L.C.U. (Mackenrodt), U.S.L., levator ani muscle, urogenital diaphragm, sphincter group.

angle. The ureter traverses the anterior margin of the surface in a preformed fascial groove (Figs. 5, 6, 7).

The anterior surface is the smallest of the three surfaces, because the levator ani muscle rises sharply in this region. The upper part of this surface fuses with the uterovaginal fascia giving the latter a wider "fixation span," while the lower part is attached to the fascia of the lateral vaginal wall. Caudally and laterally this surface is attached to the levator ani fascia.

The posterior surface is the largest of the three surface areas. It blends with the levator ani fascia. A foramen or gap is present between the ligament and the fascial fibers passing up from the levator to the vaginal fascia. A triangular space exists between the three surfaces (Figs. 3, 5, 6). The base of the triangular space faces caudally and laterally, being formed by the cranial fascia of the levator ani muscle.

In the normal adult this cavity contains areolar tissue and unstriated muscle. Smooth muscle fibers extending from the upper third of the vaginal wall are attached to the inferior aspect of the superior and posterior surfaces of the ligament (Fig. 8).

The posterior segment is the largest of the three areas, and its fascia the most attenuated because of the passage of the rectum. The most condensed fibers extend from the posterior inferior aspect of the supravaginal fascial collar, and terminate in the second and third sacral vertebrae. These fibers are known as the uterosacral ligaments. That space behind the cervix, bounded by the uterosacral ligaments laterally and the rectum posteriorly is known as the pouch of Douglas (Fig. 5). This is the bottom of the abdominal cavity; here the fascial diaphragm is thinnest. In frontal section, descending caudally from the posterior margin of the supravaginal collar is a tongue-like reef of fascia extending between the posterior vaginal wall and the anterior rectal wall and terminating in the perineal body. This caudal prolongation is known as the rectovaginal septum.

THE SMOOTH MUSCLE DIAPHRAGM

During the last 3 months of fetal life, smooth muscle tissue exists in definite masses in the subperitoneal pelvic space. The arrangement of the tissue is identical with that in the adult, except that it is much less massive and the direction of the bands varies because of the difference between the positions of the pelvic organs in fetal and adult life. The smooth muscle tissue is not confined only to the areas immediately surrounding blood vessels and nerves. Most of it is made up of strands entirely independent of these structures. When they are reconstructed and viewed from the superior aspect, the direction of the fibers leads one to consider the tissue as an imperfect "diaphragm" of smooth muscle converging on the uterine cervix.

In the adult an imperfect smooth muscle diaphragm is present and embedded in fibrous tissue, lying between the endopelvic fascial diaphragm and the superior surface of the levator ani muscle. The smooth muscle bundles which constitute this diaphragm radiate

from the uterus at the level of the internal os. The peripheral attachment of these bundles enables the tissue to be divided into three groups of fibers, anterior, lateral, and posterior groups.

The anterior fibers arise from the anterior and the anterolateral aspect of the cervix and are attached (a) to the posterior aspect of the os pubis, either directly or through the intermediary of fibrous bands, and (b) into the muscular coat of the bladder. The muscle fibers which make up this group can be subdivided into the following bundles: (a) the cervicovesical, (b) the cervicopubic, (c) the vesicovaginal, and (d) cervicovaginal (Fig. 9).

The lateral group The lateral group (which is identical with the lateral ligament of the cervix uteri—Mackenrodt) arises similarly from the lateral aspect of the cervix. It diverge and form a flattened fan of fibers which is attached by means of fibrous strands to the "arcus tendineus." This group is subdivided into an upper and lower bundle. From this group, slightly below level of internal os, fibers pass to the lateral vaginal fornix.

The posterior group The posterior group, also arising from the cervix, enters into the composition of the uterosacral ligaments or finds insertion into the rectal walls and rectovaginal septum. This group is subdivided as follows: (a) uterosacral fibers, (b) rectal fibers, (c) posterior vaginal fornix fibers, and (d) rectovaginal septum fibers.

Besides these distinctive strands enumerated, short fibers, like a fine platysma muscle, enter the anterior and posterior peritoneal layers of the broad ligament, from the corresponding uterine surfaces and end deep in the endothelium.

Dilatation of the connective tissue diaphragm, to the extent of permitting the passage of the fetal head, demands a great stretching of this poorly contractile tissue, which of itself could not assume its original dimensions as it contains little, if any, elastic tissue. The return to the normal postpartum state is assisted by the closely associated smooth muscle diaphragm which has the power of greater extensibility. The fibromuscular diaphragm is not necessarily injured in normal childbirth. Dilatation of the

uterus and cervical canal will slacken the tautness of the fibromuscular diaphragm, while return to the normal size of this viscus will renew the tension of the musculofascial diaphragm.

THE LEVATOR ANI MUSCULAR DIAPHRAGM

This "ununiform" muscular plane spans the pelvis obliquely, stretching anteroposteriorly from the symphysis pubis to the sacrum and coccyx. Laterally from the levator ani white line, extending medially and caudally to the external sphincter of the anus, to the anococcygeal raphe, the sacrum, and coccyx.

The general sloping trend of the fibers medially and caudally give this muscle a somewhat "cup-shaped" appearance, with a trough-like exit beneath the symphysis pubis—where the medial arms of the pubococcygeal

Fig. 5. Viewed from above. Showing the three surfaces of the lateral ligament. Like looking at the side of a funnel.

segment enclose two clefts. An anterior one, the urethrovaginal, and an anal one, posterior to the perineal body. While the origin of this diaphragm is fixed to bone, particularly its anterior and posterior segments, its insertion is mobile, the significance of this fact increases with parturition.

From an obstetrical viewpoint the levator ani muscular diaphragm on each side consists of three segments—an anterior or pubococcygeal, a middle or iliococcygeal, and a posterior or ischiococcygeal. These bifurcated muscles take an extensive origin from bone and fascia.

The anterior segment consists of the pubococcygeus muscle, by far the most important of the three segments. It forms the largest, strongest, thickest, and most important part of the pelvic floor. Its fibers have a bony origin from the posterior wall of the symphysis pubis beneath the levator ani white line; and

In the normal adult this cavity contains areolar tissue and unstriated muscle. Smooth muscle fibers extending from the upper third of the vaginal wall are attached to the inferior aspect of the superior and posterior surfaces of the ligament (Fig. 8).

The posterior segment is the largest of the three areas, and its fascia the most attenuated because of the passage of the rectum. The most condensed fibers extend from the posterior inferior aspect of the supravaginal fascial collar, and terminate in the second and third sacral vertebrae. These fibers are known as the uterosacral ligaments. That space behind the cervix, bounded by the uterosacral ligaments laterally and the rectum posteriorly is known as the pouch of Douglas (Fig. 5). This is the bottom of the abdominal cavity; here the fascial diaphragm is thinnest. In frontal section, descending caudally from the posterior margin of the supravaginal collar is a tongue-like reef of fascia extending between the posterior vaginal wall and the anterior rectal wall and terminating in the perineal body. This caudal prolongation is known as the rectovaginal septum.

THE SMOOTH MUSCLE DIAPHRAGM

During the last 3 months of fetal life, smooth muscle tissue exists in definite masses in the subperitoneal pelvic space. The arrangement of the tissue is identical with that in the adult, except that it is much less massive and the direction of the bands varies because of the difference between the positions of the pelvic organs in fetal and adult life. The smooth muscle tissue is not confined only to the areas immediately surrounding blood vessels and nerves. Most of it is made up of strands entirely independent of these structures. When they are reconstructed and viewed from the superior aspect, the direction of the fibers leads one to consider the tissue as an imperfect "diaphragm" of smooth muscle converging on the uterine cervix.

In the adult an imperfect smooth muscle diaphragm is present and embedded in fibrous tissue, lying between the endopelvic fascial diaphragm and the superior surface of the levator ani muscle. The smooth muscle bundles which constitute this diaphragm radiate

from the uterus at the level of the internal os. The peripheral attachment of these bundles enables the tissue to be divided into three groups of fibers, anterior, lateral, and posterior groups.

The anterior fibers arise from the anterior and the anterolateral aspect of the cervix and are attached (a) to the posterior aspect of the os pubis, either directly or through the intermediary of fibrous bands, and (b) into the muscular coat of the bladder. The muscle fibers which make up this group can be subdivided into the following bundles: (a) the cervicovesical, (b) the cervicopubic, (c) the vesicovaginal, and (d) cervicovaginal (Fig. 9).

The lateral group The lateral group (which is identical with the lateral ligament of the cervix uteri—Mackenrodt) arises similarly from the lateral aspect of the cervix. They diverge and form a flattened fan of fibers which is attached by means of fibrous strands to the "arcus tendineus." This group is subdivided into an upper and lower bundle. From this group, slightly below level of internal os, fibers pass to the lateral vaginal fornix.

The posterior group The posterior group, also arising from the cervix, enters into the composition of the uterosacral ligaments or finds insertion into the rectal walls and rectovaginal septum. This group is subdivided as follows: (a) uterosacral fibers, (b) rectal fibers, (c) posterior vaginal fornix fibers, and (d) rectovaginal septum fibers.

Besides these distinctive strands enumerated, short fibers, like a fine platysma muscle, enter the anterior and posterior peritoneal layers of the broad ligament, from the corresponding uterine surfaces and end deep in the endothelium.

Dilatation of the connective tissue diaphragm, to the extent of permitting the passage of the fetal head, demands a great stretching of this poorly contractile tissue, which of itself could not assume its original dimensions as it contains little, if any, elastic tissue. The return to the normal postpartum state is assisted by the closely associated smooth muscle diaphragm which has the power of greater extensibility. The fibromuscular diaphragm is not necessarily injured in normal childbirth. Dilatation of the

The iliococcygeus lies posterior to, and on a deeper plane than, the pubococcygeus. Viewing the pelvic floor from above (Figs. 3, 5, 6, 10) actually it is more superficial. It is attached to the arcus tendineus behind the obturator canal and is inserted into the anococcygeal body and into the margins of the coccyx, lateral and caudal to the fibers of the pubococcygeus. Occasionally this muscle retains its primitive origin from the pelvic brim. In lower animals it has a flat tendinous origin from the iliopectineal line. Since it has lost its original purpose in man it is poorly developed, and has slipped lower down on the pelvic wall. Its fascial point of attachment has become elongated, therefore, so that the fibers of origin of the muscle do not, except in a few instances, extend to such a degree as the iliopectineal line.

In most cases in the dissecting room, muscle fibers can be demonstrated only at a considerable distance from the point of origin of this muscle.

The elongated and thinned out "aponeurosis" of the iliococcygeus muscle is seen to be intimately fused with the sheath of the obturator internus muscle.

Fig. 10. Semidiagrammatic mesial section of pelvis, showing the mutual relationships of the components of the pelvic diaphragm. Notice especially the upper and lower leaves of the urogenital diaphragm.

The fusion of the remains of the aponeurosis of the iliococcygeus with the fascial covering of the obturator internus muscle forms a composite sheath of fascia, the so called obturator fascia. The line of fusion between these two fasciae is of considerable clinical importance, in that it defines the upper limit of the ischio-rectal fossa.

The so called "white line" does not accurately indicate the upper limit of the iliococcygeus muscle but rather an arrangement of its fascial investment. This fascia is subject to tension between two fixed points and has become condensed. In this instance the fascial fibers of the sheath of the levator ani form a narrow band popularly referred to as the "levator ani white line," which extends from its point of attachment on the posterior aspect of the pubis to the spine of the ischium. The white line, therefore, appears to cross the

Fig. 6. Semidiagrammatic representation of pelvic floor with right lateral cervical ligament shown in position (On the left side the fascia has been removed to show the underlying muscles.) At the lateral end of this ligament the uterine artery can be seen crossing the ureter. At the medial end of the ligament the inverted U-shaped outline is well shown. The small insert shows the ligament from behind. Note the hiatus at the lower border of the posterior surface.

from the areus tendineus in front of the obturator canal. From this origin its fibers sweep backward as three distinct bands, the most medial fibers form a U loop around the vagina

Fig. 7. Dissection. Lateral ligament of cervix uteri (Mackenrodt) viewed from above presenting superior surface. (Probe under ureter.)

and are inserted into the "central point" of the perineum with firm attachment to the cranial leaf of the urogenital diaphragm. These fibers constitute the "pubovaginales." A thin bundle is confluent with the urethralis muscle.

The intermediate fibers resemble a horse shoe attached by its anterior extremities to the pubis and encircling the rectum behind, forming a U loop around the anorectal junction. These fibers constitute the puborectalis or sling muscle, which slings the anal canal up to the symphysis pubis. Some fibers from this bundle insert into the anococcygeal raphe.

The most lateral fibers have a Y shaped insertion into the anococcygeal raphe—the margins and ventral surface of the coccyx. This muscle forms a sphincter for the vagina and anal canal, and also increases the anorectal angulation. It gives off accessory fibers to the urethralis muscle, which act as an accessory sphincter of the urethra.

Fig. 8. Dissection. Seen directly from above. Lateral cervical ligament (Mackenrodt). Uterus and uterine artery deflected posteriorly. Ureter in position. 1, Superior surface; 2, smooth muscle fibers; 3, cervicovesical junction.

The iliococcygeus lies posterior to, and on a deeper plane than, the pubococcygeus. Viewing the pelvic floor from above (Figs. 3, 5, 6, 10) actually it is more superficial. It is attached to the arcus tendineus behind the obturator canal and is inserted into the anococcygeal body and into the margins of the coccyx, lateral and caudal to the fibers of the pubococcygeus. Occasionally this muscle retains its primitive origin from the pelvic brim. In lower animals it has a flat tendinous origin from the iliopectineal line. Since it has lost its original purpose in man it is poorly developed, and has slipped lower down on the pelvic wall. Its fascial point of attachment has become elongated, therefore, so that the fibers of origin of the muscle do not, except in a few instances, extend to such a degree as the iliopectineal line.

In most cases in the dissecting room, muscle fibers can be demonstrated only at a considerable distance from the point of origin of this muscle.

The elongated and thinned out "aponeurosis" of the iliococcygeus muscle is seen to be intimately fused with the sheath of the obturator internus muscle.

Fig. 10. Semidiagrammatic mesial section of pelvis, showing the mutual relationships of the components of the pelvic diaphragm. Notice especially the upper and lower leaves of the urogenital diaphragm.

The fusion of the remains of the aponeurosis of the iliococcygeus with the fascial covering of the obturator internus muscle forms a composite sheath of fascia, the so called obturator fascia. The line of fusion between these two fasciae is of considerable clinical importance, in that it defines the upper limit of the ischio-rectal fossa.

The so called "white line" does not accurately indicate the upper limit of the iliococcygeus muscle but rather an arrangement of its fascial investment. This fascia is subject to tension between two fixed points and has become condensed. In this instance the fascial fibers of the sheath of the levator ani form a narrow band popularly referred to as the "levator ani white line," which extends from its point of attachment on the posterior aspect of the pubis to the spine of the ischium. The white line, therefore, appears to cross the

Fig. 11. Schematic representation of the sphincteric muscular group of the pelvic floor.

pubococcygeus muscle because unlike the iliococcygeus, the former has not descended. The white line in some cases is found separated by some little distance from the pelvic wall and when this is so a pouch—the “hiatus of Schwalbe”—filled with fat, exists between the two.

The D shaped opening of the anus, previous to expulsion of the fetal head, is due to extension of the fibers of the puborectalis and iliococcygeus which are inserted into the ano-coccygeal raphe.

The ischiococcygeus with the piriformis forms the muscular upholstery which closes the posterior part of the pelvic outlet. Posteriorly and caudally it is reinforced by the sacrotuberous ligament (great sacrosciatic ligament). This triangular muscle is set at almost a right angular plane to the iliococcygeus. It arises from the apex of the ischial spine and is inserted fan-shapedwise into the lateral border of the sacrum and into the lateral margins of the coccygeal bodies, conjointly with the iliococcygeus muscle.

The individual muscle sections of the pelvic diaphragm do not by any means form a uniform sheath in one plane, but overlap one another posteriorly where they join and interdigitate with the muscle fibers of the other

side. By this means the part of the diaphragm posterior to the rectum is clearly strengthened.

Morphology. In pronograde animals there are three caudal muscles; the pubococcygeus, arising from the body of the pubis, the iliococcygeus arising from the pelvic brim, both of which are tail depressors, and the ischiococcygeus, a lateral flexor of the tail arising from the ischial spine. With the disappearance of the tail in man and the assumption of the upright position, the tail muscles take over new duties and form a pelvic floor for the support of the pelvic viscera. The pubococcygeus and the ischiococcygeus muscles retain their primitive origins, but the iliococcygeus loses its attachment to the pelvic brim and gains a new attachment to the lateral pelvic wall at the arcus tendineus. While the caudal muscles gain extensive new insertions into the pelvic floor, they still retain their original insertion into the coccyx, which is the rudimentary tail. Thus, while the levator ani muscular diaphragm contributes to the support of the viscera, the muscles which constitute it are derived from the flexors and abductors of caudal end of vertebral column.

THE UROGENITAL DIAPHRAGM

The urogenital diaphragm is a relatively inelastic double-leaved fascial envelope, extending between the ascending pubic rami and beneath the subpubic arch, to whose margins it is firmly attached (Figs. 3, 10, 13 to 18). It closes over the perineal triangle, while its so called free margin extends between the ischial tuberosities, demarcating the posterior boundary line of the perineal triangle. It is perforated by the dorsal vein of the clitoris, the urethra, and vagina. It contains the pudendal vessels and nerves and the membranous urethra, the sphincter urethrae and transversus perinei profundus muscles. This latter muscle is supportive to the vaginal wall.

The pubococcygeal segment of the levator ani muscle plays on its cranial fascia into which fibers of this muscle find a firm attachment. Thus the integrity of this fascial leaf prevents within certain limits the separation of the pubococcygeal segment. The wedge-shaped, anteriorly directed diverticulum of the ischio-rectal fossa extends between the

Fig. 12. (Silhouettes) a, Android inlet; b, midpelvic plane, round; c, level of ischial spines and plane of pelvic floor, spheroidal.

pubococcygeus muscle and its cranial fascia. Its caudal fascia gives attachment to the sphincteric vulval musculature. With the body in the erect position, the urogenital diaphragm, like the os pubis and its rami, is in a horizontal plane, so that support of the pelvic viscera falls upon these structures.

THE SPHINCTERIC MUSCULAR DIAPHRAGM

While this group offers some supportive action it is primarily sphincteric in contradistinction to the levator ani muscular diaphragm which is primarily supportive and only secondarily sphincteric to the pelvic viscera. It forms sphincters for the openings of the canals which perforate the pelvic floor to reach the exterior. It is derived from the primitive sphincter cloacae, a primitive muscular ring surrounding the cloaca, which is partly attached to the bones at the pelvic outlet.

During the course of the development of the genitourinary organs a cloacal aperture exists till about the 5th week, and a sphincter muscle is arranged about it—the primitive sphincter cloacae. About this time a caudal prolongation of the transverse mesodermal bar takes place dividing the cloaca into two parts, a dorsal or anal, and a ventral or urogenital, and coincident with this change the sphincter cloacae becomes divided into dorsal and ventral divisions, the former surrounding the anal aperture and constituting the sphincter ani externus, the ventral surrounding the urogenital sinus. It is from the urogenital division that the bulbocavernosus, the ischio-cavernosus, the transversus perinei and the sphincter urethralis muscles develop (Fig. 11).

ACCESSORY STRUCTURES

Perineal body. The perineal body or central tendon of the perineum is a triangular wedge

of tissue whose base is represented by the skin surface existing between the posterior commissure of the vagina and the anterior margin of the anus. Its apex is demarcated by the line of juxtaposition of the posterior vaginal wall and the anterior rectal wall. It is made up of fat, connective tissue, voluntary and smooth muscle fibers. Laterally it receives fascial lamella from the perivaginal and perirectal fascia. The lamellar layer of the rectovaginal septum extending from the supra-apex. This structure is analogous to the hub of a wheel or the ring of a parachute, into which is inserted each one of the diaphragms constituting the pelvic floor. It has been popularly called the tendo achillis of the perineum. The perineal body is the "keystone" of support to each of the various diaphragms constituting the pelvic floor. Injury to the perineal body is reflected in each of these structures. The baby has to come down the

uterovaginal canal to make its exit. The vulva at the anterior end contains the bony untensile platform. However, the symphysis pubis opens slightly and the coccyx is displaced downward and backward. The visceral structures with their fascial attachments move upward, the muscular segment, the levator ani moves downward and backward and both segments are canalized. The pelvic floor has to be opened and closed; to be opened, it is displaced backward and downward. If it is damaged, it cannot be completely closed. A torn and damaged perineal body is going to prevent return to integrity.

Gluteus maximus muscle. The levator ani muscular diaphragm receives support from the two gluteus maximus muscles. These muscles are a source of strength capable of presenting great counterpressure to the powerful muscles of the ventral wall and the respiratory diaphragm. The lower medial fibers of the muscles pass downward and backward from the

muscular diaphragm. The fat pad is continuous with the fat of the adjacent superficial fascia. The superficial fat of perineum and the apposition of medial aspects of the thighs also act as accessory, supportive structures.

THE COURSE OF PARTURITION

The bony pelvis is a funnel-shaped bony cage with a bend resembling the elbow of a stovepipe. Its gently sloping walls and muscular upholstery offer deflecting surfaces to the fetal head during parturition. It possesses a bore, similar to that of a turbine, or rifle—the fetus representing the bullet which, passing through, must make certain turns in order to accommodate itself to the unequal bore of the pelvis.

Previous to the onset of labor the fetal head rides at ease in the "military position" above the obstetrical inlet, the posterior quadrant of which passes through the body of the first sacral vertebra, the longitudinal axis of the fetal ovoid being parallel with the vertebral column of the mother (Figs. 17, 18).

With labor established, the fetal head is first "jockeyed" into one of the oblique diameters

coccyx, separated from each other by an angle of 30 degrees and connected by tough, intervening connective tissue. They underlie each ischiorectal fossa and support the pelvic diaphragm very powerfully through the pad of fat which fills these fossae. The fat pad in the ischiorectal fossa is made up of small masses of fat with powerful strings of connective tissue fibers intervening with one another and connected with the walls of the fossa, with the perimysium externum of the internal obturator and gluteus maximus muscles and with the caudal fascia of the urogenital diaphragm, which limits the ischiorectal fossa anteriorly. The fat pad lies under the levator ani muscular diaphragm throughout its extent and so forms a cushionlike support which, though soft and pliable, transmits to the levator ani muscular diaphragm all the strength and security given it by the gluteus maximus muscles and the powerful urogenital diaphragm. These offer real strength and support to the levator ani

Fig. 17. P.S. Schematic frontal section slightly anterior to bisected anteroposterior diameter of pelvic inlet. Labor established. Head "centered" in axis of inlet. Membranes intact. of the pelvic inlet, usually the right, this being the relatively larger of the two diameters, its sagittal suture passing from the oblique to the transverse diameter of the obstetrical inlet. The passenger is then propelled along the road of birth, the axis of which is backward and downward to the ischial spines (Figs. 12c, 19) the area of least dimensions, which is also the plane of origin of the pelvic floor; then forward and slightly upward through the pelvic outlet. The bore of the road of birth causes the passenger to make three turns during its voyage, one at the inlet, a second at the ischial spines (internal rotation), and a third (external rotation) which is on the balcony of soft parts beyond the bony pelvis (Figs. 12, 14).

When the descending head strikes the pelvic floor, the muscular segments react by increased oscillations, thus temporarily assuming a horizontal plane. When the muscular

resistance is overcome, a vertical plane is assumed and the levator ani muscle is said to be "funnelled."

The levator ani muscular segments are funnelled from behind forward. The ischio-coccygeus is the first to receive the impact of the fetal head, but the head is preceded by the membranes filled with fluid forming a wedge whose narrow lower end slips into the vagina and really transfers most of the pressure onto the front of the pubococcygeus just where it passes into the perineal body. Thus the anococcygeal raphe is pushed down at its anterior end until it becomes ventral, and the ischio-coccygeus, which is set at almost a right angular plane to the ilio-coccygeus, assumes a vertical plane and acts as a deflecting surface to the descending head. With the propelling force of the contracting upper uterine segment, the head is deflected downward and forward onto the fibers of the ilio-coccygeus

Fig. 19. F.S. Membranes ruptured. Descent of head to ischial spines. Sagittal suture is in oblique plane. Further flattening and stretching of the lateral ligaments of the cervix uteri. Fibers of the levator ani muscular diaphragm changing from oblique to vertical direction. Pull being exerted on upper leaf of the urogenital diaphragm.

muscle. The fibers of this muscle slope medially and caudally; their resistance is soon overcome and the head is then shunted on to the pubococcygeal segment, which is stretched anteroposteriorly and peripherally. As the peripheral dilatation of its fibers takes place, the urogenital diaphragm is opened. The adjacent cranial leaf of the urogenital diaphragm turns upward on the sides of the vagina and has attached to it the fibers of the pubococcygeal muscle. Thus, as the vagina dilates and the pubococcygeus is dilated peripherally the cranial leaf of the diaphragm is pulled upward. The caudal diaphragmatic leaf is pushed downward as the head is propelled along the axis of the pelvic outlet (Figs. 10, 13, 14). The transversus perinei profundus muscle is flattened peripherally and stretched vertically, its fibers being dispersed between the upper and lower fascial leaves. The rectovaginal septal fibers are stretched peripherally and longitudinally. This septum can

Fig. 20. a, Transverse section of cervix and supravaginal fascia. Center, cervix. Cervix represented by light wavy lines. Fascial collar by heavy dark lines. b, Frontal section. These ligaments flatten peripherally with dilatation of the lower uterine segment and elongate with its vertical stretching.

sometimes be seen being pushed in front of the descending head, if stretched beyond its elastic capacity, this structure tears, either vertically or transversely, severing its continuity with the perineal body.

As the sphincteric group of muscles are dilated they are converted into a short muscular tube along the axis of the pelvic outlet. Their stretched fibers extend beyond the bony framework. When the biparietal diameter of the fetal head reaches the transverse diameter of the pelvic outlet, the perineum bulges for a distance of 1.5 to 2 inches. Coincident with this bulging, or "crowning," the coccyx and anococcygeal raphe are being displaced downward and backward. The posterior fibers of the external sphincter, which are attached to the anococcygeal raphe, are stretched and pull the anus open in a D-shaped fashion. At this moment the uterovaginal canal is converted into one continuous hiatus (Figs. 1, 14). The lateral ligaments of the cervix uteri are flattened peripherally and stretched vertically. The smooth muscle diaphragm is dilated spherically and the leva-

tor ani muscular diaphragm changed from an oblique to a vertical plane. The urogenital diaphragm is opened and the sphincteric diaphragm dilated spherically, followed by dilatation of Colles' fascia and the skin surface.

While the lower uterine segment starts to unfold at the fourth month of intrauterine life, it is only fully developed as a mechanical product of labor. Synchronously with the unfolding of the lower uterine segment, a hypertrophy and a hyperplasia of the supra-cervical fascial collar takes place. As the lower uterine segment widens and elongates, the fascial collar correspondingly follows it. With the establishment of labor the lateral ligaments of the cervix uteri have grown and stretched considerably in size so that, metaphorically, they may be likened to the stretching of a rubber to that of a rubber boot. At the moment of expulsion of the fetal head, the uterovaginal canal is converted into one continuous hiatus, the lateral ligaments of the cervix uteri are flattened peripherally and elongated vertically. When the baby is expelled, the lower uterine segment regains its contractility and its calibre is diminished with a corresponding contractility and reduction in size of the stretched endopelvic fascial structures. The lateral ligaments of the cervix uteri contract in their vertical length and regain their axial arrangement in the horizontal plane (Fig. 15).

With the expulsion of the placenta, the caliber of the lower uterine segment is further reduced. The cervix rises to the ischial spines. The lateral ligaments of the cervix uteri assume their pregravid axial arrangement (Fig. 16). The anterior and posterior fundal walls are in apposition, being separated only by filamentous bands of fibrin and blood clot. Further involution follows provided the anatomical integrity of the supporting pelvic structures has been maintained. The fascial diaphragm is likewise favorably affected by involution or unfavorably affected by subinvolution. Trauma or infection of the isthmocervical canal will likewise affect the adjacent fascial supports. Should the fascial and levator ani muscular diaphragms be traumatized and unrepaired, prolapse will inevitably follow.

THE CLINICAL SIGNIFICANCE OF THE PELVIC FASCIA IN OBSTETRICS

The endopelvic fascia—as an extensive fixation apparatus moors the uterus to the levator ani white line and to the pelvic floor.

The lower uterine segment and its fascial supports represent an active force in determining the axis along which the fetal head must descend through the pelvis.

The fascial attachments of the lower pole of the uterus influence the fetal ovoid in its descent through the pelvis.

The fascial supports of the uterus have received many names. Among others, the following designated titles have been applied: the parametrium (Vitchow), the cardinal ligaments (Kock), the vascular sheath (Charpy), the hypogastric sheath (Pierre Delbet), the uteroiliac process (Savage), ligamentum lata, tunica vasorum uteri (Merkel), ligamentum transversale colli (Mackenrodt), the sustentacular apparatus (Bonney), the lateral cervicopelvic ligaments, the upper pelvic floor (Polls).

The anglicized version, namely, "the lateral ligament of the cervix uteri" is a more meaningful and purposeful terminology, and in keeping with the principles accepted at Basle, in 1895, by the Anatomical Society.

Because of its fixation to the elastic levator ani white line laterally, and to the supravaginal cervix medially, with the formation of the lower uterine segment this fascial diaphragm hugs the lower uterine segment, and is elongated in a cranial direction assuming somewhat the topographical outline of an inverted expanding funnel or inverted Medici collar. Its weakest point is posteriorly between the uterosacral ligaments where the fascial collar is thinnest. Metaphorically, it may be said to be stretched from the "size of a rubber to that of a rubber-boot."

The lower uterine segment is formed from the body of the uterus, the isthmus and cervix. In full development it is a mechanical product of labor, being the passive or accordianated portion of the cervicouterine canal. The contraction ring not only marks the line of demarcation between the contractile part of the uterus and the lower uterine segment but also delineates the cranial attachment of the

THE USE OF TYROTHRIN IN SURGICAL INFECTIONS

DONALD D. KOZOLL, M.D., KARL A. MEYER, M.D., F.A.C.S., WILLIAM S. HOFFMAN, Ph.D., M.D., and SEYMOUR LEVINE, M.A., Chicago, Illinois

THE peculiarities of a surgical infection are such that they frequently respond best to agents applied directly to the site of infection. With the new therapeutic era opened by the antibiotics, interest in the development of locally applied antibiotics was only natural. Among the first of these to be discovered was gramicidin, described by Dubos in 1939. It was found to be lethal to gram positive cocci (7, 8, 10, 11, 13, 16, 22) and effective in the treatment of a large variety of streptococcal lesions of the skin, sinuses, pleura, and bone (9, 12). The material was not destructive in its effect on tissues except for a pronounced hemolytic effect upon erythrocytes; removal of the hemolytic factor resulted in a loss of its bactericidal powers (14). In its antibacterial behavior it acted like an anionic detergent (15). In comparison with another closely related antibiotic, tyrocidin, gramicidin was found to be less stable, slightly more cytotoxic, and highly insoluble; tyrocidin could keep gramicidin in suspension and had more of an inhibiting effect on certain gram negative flora.

It was later found that the crude material which contained both gramicidin and tyrocidin could combine the bacterial potency of the former with the stability and solubility of the latter. The crude material—tyrothricin—represents the form in which these antibiotics are now being applied. Preliminary reports have indicated a wide field of usefulness of this drug (5, 9, 19, 22) but in the enthusiasm for the use of penicillin, few controlled clinical studies have been undertaken to evaluate this antibiotic, in spite of the fact that it offered certain theoretical advantages over penicillin.

From the Departments of Surgery of the Cook County Hospital, Northwestern University Medical School and Cook County Graduate School, from the Hektoen Institute for Medical Research of the Cook County Hospital, and from the Department of Bacteriology, University of Illinois.
Dr. Kozoll, Abbott Fellow, Department of Surgery, Northwestern University Medical School. An abridgment of a thesis submitted by Dr. Kozoll to the Graduate School of Northwestern University for the degree of Master of Science in Surgery.

In the first place, tyrothricin has been found to have a more rapid lethal effect upon sensitive organisms. Second, because of low absorption and penetration through tissues, a higher local concentration could be attained. A decreased excretion would also enhance the local concentration, a greater stability ensures prolonged action, and because of the high dilutions at which tyrothricin is still effective, it becomes clinically an inexpensive antibiotic.

The following study was outlined to investigate a specific tyrothricin preparation made available to use for this purpose:

1. To observe the clinical effectiveness of tyrothricin in the treatment of a variety of surgical lesions as judged by changes in the exudate, area of the wound, granulation, and pain.
2. To observe the effect of tyrothricin upon normal and inflamed tissues.
3. To observe signs of local and systemic toxicity.
4. To study the effect of tyrothricin upon the bacteriological flora of the wound.
5. To observe evidences of hemolysis by following the changes in the hematocrit, hemoglobin, and icteric index.
6. To compare tyrothricin with other methods of treatment.

METHOD OF STUDY

The project was undertaken by a team consisting of two nurses, a bacteriologist, a hematological technician, a photographer, and a surgeon. The same nurses dressed the wounds to standardize the method of dressings, the obtaining of cultures, and the preparation of the solutions. The same bacteriologist carried out the bacteriological studies throughout the period of the study. The surgeon selected all cases for treatment and determined the clinical result.

The tyrothricin used in this study was furnished to us as a 2.5 per cent alcoholic solution in a sterile ampul containing 20 cubic

centimeters of the material. This was added to a liter flask of sterile distilled water, thus making a solution that contained approximately $\frac{1}{2}$ milligram of tyrothricin per cubic centimeter of solution. Toward the end of the study in a few cases, a more concentrated preparation was used (1 mgm. per c.e.) or 40 cubic centimeters of the 2.5 per cent solution diluted to a liter. This was done for comparative purposes to note the effect of the stronger solution on the speed of healing. All solutions were made up freshly each day and any unused solution was discarded at the end of the day.

At the beginning of tyrothricin therapy, all wounds were photographed. The photographs were identified in the same manner as roentgen-ray films and a metric scale on the marker provided a means of permanently recording the size of the wound, which we found correlated well with actual measurements of the wound, for the differences recorded far exceeded the possible error. Special mimeographed sheets provided columns for entries of pertinent details of the clinical history and permitted daily entry of data concerning the treatment, changes in the wound, the quantity of the drug used, temperature, pulse, respiration, and all the laboratory data. The photographs were retaken at weekly or biweekly intervals as indicated. Cultures and venous blood for hematological study were also taken before the start of the therapy.

Tyrothricin was used in the form of a wet gauze dressing. The quantity of solution necessary to saturate the gauze was measured in a sterile graduate before application. The moist gauze was then packed loosely into the wound, an absorbent placed over the gauze, followed by a layer of cellophane, parchment, or wax paper to control evaporation or loss of tyrothricin solution. Dressings were held in place by gauze rolls, adhesive, binders, or splints as the lesion required. Dressings were changed daily by the same personnel.

The bacteriological procedure was carried out as follows. The nurse dressing the wound was carefully instructed to remove the same amount of exudate from approximately the same area of the wound so that the bacteriological counts might be standardized as much

as possible. At first the cultures were taken daily, but we soon learned that cultures taken every 2 or 3 days were frequent enough. The exudate was recovered by a dry sterile swab which was immediately placed into a test tube containing 2 cubic centimeters of sterile distilled water to help keep the cultures moist. All swabs reached the bacteriologist within 1 hour from the time they were taken from the wound. The bacteriologist agitated the swab in the water to displace as many of the bacteria as possible, and then the swab was placed in a tube of brain broth. The brain broth was incubated at 37 degrees C. for 24 hours after which a gram stain was made and examined microscopically. One tenth cubic centimeter of the distilled water containing the organisms was inoculated deeply into melted agar containing 0.2 cubic centimeter of blood, and poured into a sterile plate. The plate was incubated for 48 hours aerobically at 37 degrees C. after which time the colonies were counted. When it was anticipated that the infection was extremely heavy, appropriate dilutions of the original samples were made in distilled water. A special effort was made to differentiate streptococci, staphylococci, diphtheroids, and gram negative bacilli, particularly *Pseudomonas pyocyaneus*. A 4 millimeter loopful of the specimen was streaked on a blood agar plate and incubated aerobically at 37 degrees C. for 48 hours. At the end of this time well isolated colonies of varying morphology were transferred to blood agar slants and identified (2). At first a second plate was streaked and incubated anaerobically in a platinum catalyst type anaerobic jar, illuminating gas being used instead of hydrogen gas. It was soon found that so few of the wounds possessed an anaerobic flora, that it was unnecessary to use anaerobic technique routinely. Instead, the brain broth culture, described in the foregoing, was examined and when any suspiciously appearing gram positive rods were found, an anaerobic streak plate was prepared from the brain broth. Anaerobes were identified by Reed and Orr.

Hematological studies were carried out on venous blood drawn before the start of the therapy and at weekly intervals thereafter.

Heparin was used as the anticoagulant for plasma. Determinations included the sedimentation rate, hematocrit, hemoglobin, total serum protein, and icteric index. The sedimentation rate was performed by the Wintrobe method, correction being made for abnormally low hematocrits. Hemoglobin determinations were made on heparinized venous blood, the photoelectric method being used. Total serum proteins were studied by the specific gravity method of Barbour-Hamilton. Icteric indices were carried out on serum in the usual manner.

MATERIAL

The clinical material studied is listed in Table I. It consists of 77 cases of surgical infections of a wide variety such as is encountered in the charity wards of a general hospital. No deliberate attempt was made to select cases, but certain fundamental surgical principles were followed: i.e., only draining infections which communicated with the exterior were considered. At first no attention was paid to the blood supply of the part but it was soon learned that the treatment was doomed to failure in the presence of gangrene. Infected postoperative wounds were the most frequent lesions treated, of which there were 19. Infected varicose ulcers were next in frequency and constituted a group of 10 patients. There were 7 patients with cellulitis and 7 with abscesses, 5 with empyema and 5 with burns. The remainder were quite varied in nature. All patients were hospitalized for the entire period of study and received no other therapy conjointly with the tyrothricin therapy.

There were 49 white and 28 negro patients, 47 being males and 30 females. The oldest patient was 79 years and the youngest 2 years of age. There was an additional group of patients studied privately in other hospitals but these are not included for statistical appraisal because either the photographic evidence or the bacteriological studies were incomplete.

The majority of these patients were referred to us after their lesions had proved refractory to a variety of other methods of treatment, which included the use of Dakin's solution,

Dakin's with saline, saline packs, sulfonamides, xeroform gauze, vaseline gauze, boric acid solution, ultraviolet light, and parenteral penicillin. These, therefore, act as control measures in evaluating the drug under investigation. Included were 6 cases with bilateral lesions in which one lesion was treated with tyrothricin and another with a control preparation. These we feel offer more crucial tests of comparison than a parallel series of patients with unilateral lesions. The variability among patients and types and degree of infections is so numerous that only a series of several hundred cases would offer statistically significant evidence.

RESULTS

A. Clinical. The criteria for clinical improvement in the treatment of the infection included the disappearance of all visible signs of infection, the decrease in the amount of exudate, the growth of viable healthy granulation tissue, the growth of epithelium over the granulation tissue, and a decrease in the size of the wound as verified by actual measurement. According to these criteria, clinical results were placed in three categories: excellent, fair, and poor.

Table I lists the various infections treated with the results evaluated as indicated above. Of 77 cases treated, 50 (65 per cent) showed excellent results, 8 (10 per cent) showed fair results, and 19 (25 per cent) showed poor results. It will be noted that 18 out of 19 cases of postoperative wound infection responded with excellent results and one gave a poor result. In the 10 cases of infected varicose ulcers, there were 7 excellent results with tyrothricin treatment, 1 was fair and 2 were poor. All of 7 cases with cellulitis responded excellently, whereas of the 7 cases of abscesses, 5 showed an excellent result and 2 poor, the latter were ischiorectal abscesses in debilitated patients. Four of the 5 patients with empyema and open drainage responded well to tyrothricin. In 1 case of an abscess due to Friedlaender's bacillus infection, the result was only fair. Of 5 infected burns treated, the result was excellent in 1, fair in another, and poor in 3. All 3 cases of decubitus ulcers responded excellently. Two of three lacerations

statistical evaluation. The short time of treatment in the group with poor results was due to the fact that in many of these cases either death or some complication supervened which required discontinuance of treatment.

The speed of healing was usually proportionate to the initial size of the wound. The general clinical impression was gained that tyrothricin solution directly or indirectly speeded the formation of granulation tissue. Epithelization was also promoted so that skin grafting was necessary in only 5 of the 30 cases showing excellent results. Even the decision to do skin grafting was motivated by a desire to shorten the period of hospitalization. By indirect measurement of all wounds as recorded on photographs (instead of direct measurements of the wounds themselves) the percentage decrease in the area of the wound varied from 36 per cent to 100 per cent in the cases showing excellent results, with an average of 70.7 per cent. The number of cases in the group with fair results do not permit statistical evaluation, but the clinical impression was that there was appreciably less healing. In the group with poor results there was little decrease in the size of the wound, and in some cases the wound increased in size.

The 6 cases with bilateral lesions in which tyrothricin was applied on only one lesion merit detailed analysis. The first of this group was that of a severe pyocyanous infection of both hands following third degree burns. The

responded well whereas the third did not. Of 2 secondarily infected lutetic ulcers which had not responded to antilutetic therapy alone, 1 showed an excellent result with tyrothricin, and the other a poor one. The patients with carbuncles responded only fairly. Three patients with osteomyelitis (diabetics) and 1 patient each with an infected fracture, an x-ray burn, a carcinomatous ulcer, tenosynovitis, and a perinephric fistula, all did not improve with tyrothricin therapy.

Table II presents the length of treatment required in each of the groups classified as to result. It is to be noted that of the patients with excellent result, 4 responded within 1 week of treatment, 11 within 2 weeks, 6 within 3 weeks, and 16 within 4 weeks of treatment. In other words 37 out of 77 patients responded to tyrothricin with excellent results within 1 month; 13 others required an additional month. The group with fair results is too small for

*Total number of organisms will be greater than total number of cases because each wound will vary as to the number of different organisms it contains.

right hand was treated with tyrothricin while the left was treated with equal parts of boric acid and vinegar; the tyrothricin treated hand did much more poorly and tyrothricin treatment had to be discontinued. The second case of this group was that of a patient with bilateral varicose ulcers of almost identical initial size (Fig. 8). The right ulcer, which was treated with tyrothricin, showed a much more rapid clearance of exudate, granulation, epithelization, and disappearance of pain, than did the left ulcer which was treated first with Dakin's saline solution and then saline solution alone. Also bacteriologically, the tyrothricin treated wound responded more favorably. Case 3 of this group was that of an infected epidermophytosis and edema of both legs. There was no apparent difference between the leg treated with tyrothricin and the one treated with saline, although the former was the more seriously involved. Case 4 of the group (Fig. 17) involved a patient with varicose ulcer on the right leg measuring 36.1

square centimeters and one on the left leg measuring 7.4 square centimeters. The right ulcer was treated with tyrothricin and the ulcer healed completely in 3 weeks while at the end of the same period the left ulcer, which had been treated with saline, still measured 2 square centimeters. The fifth case was one of hemiplegia and decubitus ulcers on both heels; the right ulcer, treated with tyrothricin for 4 weeks, showed an 80 per cent decrease in area and filled with granulation tissue, while the left one, treated with saline during that time, was still purulent and had not decreased in size. The remaining case of this series was another one of bilateral varicose ulcers in which the ulcer treated with tyrothricin responded about as well as the one treated with Dakin's saline solution although the former wound was by far the larger (Fig. 19).

In the few experiments in which the strength of tyrothricin solution was doubled (1 mgm. per c.c.) the speed of granulation appeared to increase. For example, if the size of the lesion

in Figures 9, 13, and 20 is compared with some of those in earlier cases (Figs. 2, 3, 7) the increased speed with which these larger lesions became granulated may be attributed to the stronger solution. Similarly, in cases in private practice where a change of tyrothricin dressing could be carried out every 4 hours, a more rapid healing and granulation was noted. Neither the increased strength of the solution nor the more frequent change of dressing produced any tendency to local or systemic reactions.

One patient not included in the series under experimental investigation is of particular interest. The patient was a 29 year old white female who had a hemolytic streptococcal (Meleney) gangrene involving the entire thickness of the abdominal wall of the right lower quadrant down to the musculature, and ex-

tending onto the right thigh and vulva. The patient had received every therapeutic adjunct available including zinc peroxide, sulfadiazine drugs locally, orally, and intravenously, and parenteral penicillin. Within 8 days of tyrothricin therapy (applied every 4 hours night and day) all signs of necrosis and cellulitis had disappeared, the entire ulcerated area was covered with healthy granulation tissue, and the patient for the first time in several weeks did not require morphine for change of dressings and expressed the desire to get out of bed.

B. Bacteriological. The varieties of organisms encountered in each of the various types of lesions and their relative frequency is indicated in Table III. It will be noted that *Staphylococcus aureus* was found most frequently, then the diphtheroids, followed by *Pseudomonas pyocyaneus*, beta hemolytic streptococcus, *Staphylococcus albus*, and alpha nonhemolytic streptococcus. Though the flora in any given patient was identified with consistency, the colony counts at times show unusual variations. This was thought to be due either to an accidental difference in the quantity of exudate removed with the swab or to the pleomorphic nature of the diphtheroids which frequently took on the morphologic features of staphylococci or streptococci. For this reason, in a number of cases, though the total colony count was always estimated, the individual organisms were identified solely as being present or absent.

The detailed effect of treatment upon individual groups of organisms is presented in tabular form in Table IV. It was readily apparent that the beta hemolytic streptococcus was the most susceptible organism treated, followed by the *Staphylococcus aureus*, and then *Staphylococcus albus*. Tyrothricin appeared to have little favorable effect upon gram negative flora as the pyocyaneus and diphtheroids; in fact, these two organisms demonstrated a pronounced tendency either to proliferate or to make their initial appearance in the course of treatment.

A correlation between bacteriological and clinical results was also seen in studying the results indicated in Table IV. For, while all hemolytic streptococci either were killed or decreased in the group that gave excellent

Fig. 1. Infected traumatic laceration of the hand treated with tyrothricin. After 11 days of treatment there was no significant decrease in the size of the wound but such a marked clearing of all exudate and growth of granulation tissue, that a skin graft was attempted which resulted in a 90 per cent "take." A decrease in the bacteriological colony count was noted.

clinical results, the results in the group that showed poor clinical effect were also poor from the bacteriological point of view. The same correlation could be deduced from studying the responses of *Staphylococcus aureus* to tyrothricin.

The bacteriological findings in the patients with bilateral lesions presented findings of particular interest. In the patient with burns due to frostbite of both hands, the hand treated with tyrothricin revealed before treat-

ment 165,120 colonies of *Staphylococcus albus*, *pyocyaneus*, and *diphtheroids*; after treatment, culture showed less than 100 colonies of *Staphylococcus albus*, but over 1,000,000 colonies of *pyocyaneus* (principally) and *diphtheroids*. The left hand which was treated as the control showed at the start 750,000 colonies of *Staphylococcus aureus*, *pyocyaneus*, and *diphtheroids*, and this rose to 1,008,000 with the same flora. The second case (Fig. 8) bilateral varicose ulcers, showed

Area of wound—sq. cm	16	25.8	80	23
Treatment	Dakin's saline	1,285 mgm. tyrothricin	Saline dressings, sulfathiazole	2,050 mgm. tyrothricin

Fig. 7. A, An infected traumatic laceration in a malnourished vagrant which had not responded to treatment with Dakin's saline solution. Twenty-five days' treatment with tyrothricin caused a complete disappearance of all necrotic tissue and exudate and complete replacement by granulation tissue. B, A decubitus ulcer due to a plaster cast which recurred several times over a period of 4 years. After 25 days' treatment with tyrothricin all necrotic tissue had disappeared in the denuded muscles and the tendons were covered by a thick layer of granulation tissue. Skin grafting was subsequently attempted but was only partially successful, presumably due to the high count of *Pseudomonas pyocyaneus*. A laricidal effect upon *Staphylococcus aureus* was demonstrated in both cases.

on culture, 2,700 colonies of *Staphylococcus albus* in the right wound and 1,300 colonies of *Staphylococcus aureus* and *citreus*. The right wound was treated with tyrothricin for 35 days, after which time culture of the wound no longer contained *Staphylococcus albus*, but 1,600 colonies of *pyocyaneus* and 1,800 colonies of diphtheroids. The left wound was the control and after 35 days' culture of it showed 100 colonies of *Staphylococcus aureus*. The third case of this group was that of a secondarily infected epidermophytosis of both legs; the right leg was treated with tyrothricin and the bacteriological count, which was 200 colonies of *staphylococcus* and diphtheroids, rose to 13,000 colonies with the appearance of *pyocyaneus*. The control leg was treated with saline and the initial bacterial count of 100 colonies of *Staphylococcus aureus* rose to 1,000,000 colonies of *Staphylococcus aureus*,

pyocyaneus, and diphtheroids. Case 4 of this group (Fig. 17) was another with bilateral varicose ulcers. The right wound was treated with tyrothricin for 20 days and a bacteriological count of 70,000 colonies of *Staphylococcus aureus* and diphtheroids changed to 576,000 colonies of *pyocyaneus* and diphtheroids with complete disappearance of the *Staphylococcus aureus*; the left wound was treated with saline and the initial bacteriological count of 1900 colonies of *Staphylococcus aureus* and diphtheroids rose to 1,000,000 colonies of the same organisms plus *pyocyaneus*. In Case 5 with bilateral decubitus ulcers, the right wound was treated with tyrothricin for 28 days during which time the count rose from 100 colonies of *Staphylococcus albus* and *aureus* and diphtheroids to 4,200 of the same flora. The left wound, treated with saline as a control, had an initial count of 200

Fig. 8. Bilateral infected varicose ulcers of almost equal size which had not responded to Dakin's saline dressings. Right leg was selected for treatment with tyrothricin while left leg was employed as a control. Right leg showed a more rapid healing so that at the end of 35 days of treatment the right ulcer had decreased 90 per cent in size whereas the left ulcer had decreased 70 per cent. A more effective bacteriostatic influence was apparent in the tyrothricin treated wound than in the control.

colonies of *Staphylococcus aureus* and diphtheroids, which rose to 56,000 colonies of the same organisms plus pyocyanus. The sixth case (Fig. 19) of this group was that of bilateral varicose ulcers; the right and larger wound was treated with tyrothricin for 28 days and a bacteriological count of 160,000 colonies of *Staphylococcus aureus* and hemolytic streptococcus changed to one of 1,000,000 colonies of pyocyanus with complete disappearance of the staphylococcus and streptococcus. The left ulcer was treated with Dakin's saline solution with an initial bacteriological count of 172,800 colonies of the same flora as the right wound which changed to a count of 26,000 pyocyanus and a similar disappearance of staphylococci and streptococci.

C. *Hematological.* Hematocrit determinations were made in 48 of the 77 patients treated at the beginning and at weekly intervals after treatment. The patients had received quantities of tyrothricin varying from 177.5 milligrams to 6,905 milligrams in a period varying from 7 to 48 days. Significant changes in the hematocrit (more than 3%) occurred in 14 of 48 cases studied; in the re-

mainder the hematocrit varied slightly or none at all. In 14 cases where the hematocrit changed, a rise was noted in 8 and a fall in 6. There was no relationship to dose of drug administered, period of administration, type of infection, and therapeutic result. One may deduce, at least in so far as the hematocrit is a criterion, that there was no apparent hemolysis produced in these patients as the result of tyrothricin therapy.

Hemoglobin determinations were carried out in the same series of 48 patients, and changes of 2 grams per 100 cubic centimeters or more were present in 15 patients; in 6 the hemoglobin decreased and in 9 it increased. Again there was no significance in these changes. In the main, hemoglobin changes paralleled the changes in the hematocrit.

Sedimentation rates were determined in the same series of 48 patients and recorded as millimeters per hour. In all but 1 case the initial sedimentation rate was found elevated above normal. In only 1 case did the sedimentation rate fall 10 millimeters or more whereas in 8 cases it rose 10 millimeters or more. This test, as a criteria of the treatment

Fig. 11. This decubitus ulcer of the right hip of a 27 year old colored female failed to respond to a variety of therapeutic measures over a period of 8 months, during which time she was bedridden. Within 1 month of treatment with tyrothricin there was a clearance of all necrotic exudate and at the end of 55 days of tyrothricin treatment there was a 76.7 per cent decrease in the size of the wound and the patient was ambulant. A bacteriocidal effect upon the hemolytic streptococci and Staphylococcus aureus present in this case was demonstrated.

of the infection, was not of value within the period it was used.

Total serum proteins were studied with the objective in mind of eliminating hypoproteinemia as a factor in impaired wound healing and to follow the effect of infection upon hyperproteinemia. Eleven of 48 patients thus

studied presented an initial total serum protein of less than 6.5 grams per 100 cubic centimeters, and 3, levels more than 8.0 grams per 100 cubic centimeters; in the course of treatment the subnormal values tended to rise to normal and the elevated ones decreased. In the group of 48, a total of 6 patients showed a

Fig. 13. Marked cellulitis of the lower leg and foot of a diabetic. This lesion was treated with a stronger thyrothricin solution (1 mgm./c.c.) which resulted in a rapid disappearance of all necrotic tissue and exudate and replacement by granulation tissue. A 67 per cent decrease in the size of this large wound occurred in 56 days, at the end of which time a skin graft was successfully performed. A pronounced lethal effect upon *Staphylococcus albus* and *aureus* was noted.

drop in total serum proteins of 0.5 gram per 100 cubic centimeters, and a similar increase in 13 patients. The most marked cases of hypoproteinemia were seen in patients with overwhelming lesions such as eviscerated abdominal wounds, empyema, and cellulitis.

In 48 patients studied, the icterus index showed a rise above normal in 2 instances. One was in a patient with Buerger's disease who received 1,000 cubic centimeters of blood after a lumbar sympathectomy. The other was in a patient with an infected burn of the trunk and arms. Neither patient showed clinical signs of jaundice; nevertheless treatment was discontinued.

D. Reactions. Only 3 instances of reaction which could be attributed to thyrothricin treatment were seen. One was in a draining thoracotomy wound following empyema; within 24 hours after the initial introduction of 15 milligrams thyrothricin in 30 cubic centimeters of distilled water into the pleural cavity, a generalized maculopapular rash occurred which was associated with intense itching and sub-

sequent scaling. Treatment was discontinued in this case. However, 5 more chest wounds treated with thyrothricin showed no such complications. A second reaction was seen in a patient treated with 225 milligrams of thyrothricin in 450 cubic centimeters distilled water over a period of 3 days. At the end of this time the patient's leg became erythematous and warm and developed a temperature of 103.2 degrees F. This condition disappeared upon discontinuation of treatment. The third complication was seen in a patient with a huge abscess of the thigh (Fig. 9). After several weeks of treatment, a maculopapular rash developed about the wound edges. Because of the lack of subjective complaint and the excellent response in the wound, treatment was continued. The rash eventually disappeared.

DISCUSSION

In the selection of the type of lesion suitable for therapy with thyrothricin, the following considerations should be kept in mind: (1) Is the lesion an open wound? (2) Is there ade-

quate drainage? (3) Is there adequate circulation? (4) What is the bacteriological flora? (5) How acute is the infection?

Tyrothrin is an antibiotic which is suitable only for topical application, does not penetrate tissues, is not excreted, and depends upon maximal local concentration for its bacteriocidal effect. For these reasons, one cannot anticipate successful responses in lesions in which the source of infection does not communicate with the surface as in small fistulous tracts, undrained abscesses, unopened carbuncles, tendon sheath infections, and other infected lesions beneath the parietes. Furthermore, since tyrothrin is not indefinitely stable at room temperature and the best results are procured with frequent dressings, wounds for which it is best suited will be those which permit frequent changes of dressings or irrigations. For example, it would not lend itself well to a closed wound which is to heal by primary intention, or in the modern treatment of burns where infrequent dressings are regarded as desirable to minimize secondary infection. If a maximal local concentration of the drug must be maintained, it is apparent that the drug will be less effective when used solely as an irrigant. Herrell (9) found the material less effective in the treatment of sinusitis than in other lesions, but attributed the difference to more resistance on the part of the *Staphylococcus aureus*; however, the fact that

the drug could not be retained within the sinuses for a significant length of time also be operative. The fact that tyrothrin is hemolytic when absorbed interdicts its use in intrapleural injections in cases of clostridia, pyemias or in peritoneal infections, for which penicillin has been recommended.

Fig. 14a. Roentgenogram of the chest after 21 days of treatment indicated the disappearance of the abscess. Hemolytic streptococci were the only organisms isolated. The patient was discharged on the 21st day, completely recovered.

Fig. 19. Bilateral varicose ulcers which had been repeatedly treated over a period of years. The tyrothricin treated ulcer (right) was the larger but granulated in the same period of time as the smaller lesion. The lesions demonstrated bacteriocidal effects on the same organisms.

The surgical principles of the treatment of pus under pressure were adhered to in this study. In every instance adequate drainage or débridement was carried out; first, to avoid the destructive effects of pus under tension, and second, to increase surface contact between the medicament and the wound.

Tyrothricin was always used following such drainage and never in place of it. With the poor penetration power of tyrothricin, this principle will apply even more. Neither exudate nor necrotic tissue appeared to interfere with the action of tyrothricin; in many instances areas of necrosis were replaced by

Fig. 20. Popliteal abscess which was treated by incision and tyrothricin dressings. The defect extended down to the muscular compartments, but in 50 days of tyrothricin treatment, all exudate had been cleared and the wound sufficiently well granulated for skin grafting. Here again a bacteriocidal effect upon hemolytic streptococci and Staphylococcus aureus was shown.

granulation tissue without the aid of débridement. Adequate blood supply was found to be

An adequate blood supply was found to be as essential with this method of treating wounds as with all others. Every case in which the infected wound was associated with an impoverished blood supply, such as Buerger's disease, and arteriosclerotic gangrene, showed clinical failure. In fact it appears that one of the reasons for the high rate of excellent results with infected postoperative abdominal wounds was the relatively large blood supply in such areas, in contrast to the relatively poor supply in lesions of the extremities. All this implies that thyrothricin can only augment the ability of the body to ward off an infection and that an adequate blood supply is necessary to mobilize the factors of resistance and the proper nutrient substances.

It is important to determine the bacterial flora of the lesion before proceeding with tyrothricin therapy even though most of these infected wounds contain staphylococci. The nature of the predominant bacterium found gives some prognostic information. Our results demonstrate the greater effectiveness of tyrothricin upon hemolytic streptococcus, *Staphylococcus aureus*, and the *Staphylococcus albus* in the order named, and little effect upon all others. The presence of a predominantly gram negative infection, such as pyocyanus and coliform organisms militates against the use of this drug. Finally, since the progress of the wound from a clinical point of view has been found to correlate well with the disappearance of the most pathogenic organisms, repeated bacteriological cultures would aid in checking the progress of treatment.

Acute infections differ from chronic infections in many respects which are of importance in the response to any treatment. Acute infections are more apt to be superficial, to be spread over a wider surface area, to be surrounded by less connective tissue, to contain exudate with pathogenic bacteria, and to produce symptoms which attract early treatment. In contrast, chronic infections are usually more localized, surrounded by a less permeable layer of granulation tissue, contain more necrotic tissue, are more apt to contain a variety of organisms and to leave the patient

in a debilitated condition. Upon theoretical grounds, then, an acute infection should respond better to treatment with thyrothricin than a chronic one; this was actually found to be true.

From the frequency of the growth of pyocyanus in these wounds it would appear that this organism, which is normally a saprophyte, is given a chance for greater growth after the streptococci and staphylococci have been destroyed. Although the organism is usually nonpathogenic there is evidence that it interferes with successful skin grafting. In this series two skin grafts which were only 50 to 60 per cent successful had high bacteriological counts of pyocyanus (Figs. 7B), while 2 cases without significant numbers of pyocyanus organisms had 90 per cent or better "takes" (Figs. 1 and 2).

CONCLUSIONS

CONCLUSIONS

1. Tyrothricin was used as a wet dressing in the treatment of 77 patients with surgical infections, the majority of which had failed to respond to previous methods of treatment. (a) Fifty of the 77 patients (65 per cent) had excellent clinical results. (b) Eight of the 77 patients (10 per cent) had fair clinical results. (c) Nineteen of the 77 patients (25 per cent) had poor clinical results.

2. Tyrothricin, when used on one of the bilateral lesions in 6 cases, produced in 5 either a more rapid rate of healing, less pain and exudate, or a greater bacteriocidal effect than the other contralateral lesion.

3. Tyrothricin was most effective in hemolytic streptococcal lesions, next in those with staphylococcus aureus and albus. It was ineffective when the preponderant organisms were gram negative.

4. Tyrothricin appeared to encourage the growth of *Bacillus pseudomonas*, *pyocyaneus*, and diphtheroid organisms.

5. Tyrothricin was not found to produce anemia or hemolysis in the type of lesions studied. This treatment was associated

6. Tyrothricin treatment was associated with mild skin reaction in 3 patients; these reactions disappeared when treatment was discontinued in 2 instances, and in spite of continuation of therapy in the third.

7. Tyrothricin is recommended as a non-toxic, noninjurious antibiotic agent for local use in the treatment of surgical infections, if these meet the following criteria: (a) the wound is open, (b) there is adequate surgical drainage, (c) there is adequate blood supply, (d) the predominant organisms are streptococci or staphylococci or both.

THE IDENTIFICATION OF CLOSTRIDIUM WELCHII IN MIXED CULTURES AND DÉBRIDED TISSUE AND DETERMINATION OF SENSITIVITY OF THE ORGANISM TO PENICILLIN

GEORGE HELLER, Captain, Sn.C., A.U.S., Brooklyn, New York, MONROE E. FREEMAN,
Major, Sn.C., A.U.S., NATHANIEL H. SHOPE, Technical Sergeant, Medical Department,
A.U.S., ROBERT H. KINDRICK, Technical Sergeant, Medical Department, A.U.S.

DURING recent military operations in Europe, this laboratory received a large number of mixed cultures from the débrided tissue of battle wounds; the majority of these contained *Clostridium welchii*. Although the diagnosis of gas gangrene is essentially a clinical problem, Altmeier pointed out that dressings, casts, and splints make observations so difficult that gas gangrene developing under a cast may escape detection for 48 to 72 hours. Because of these difficulties a rapid bacteriological method for identifying gas gangrene organisms may be an aid in the management of contaminated wounds.

A number of rapid bacteriological methods for the identification of *Clostridium welchii* have been employed. But they have certain disadvantages for use in forward military installations. The procedures of Altmeier and Fels depend on the production of "stormy fermentation" in milk. However, Reed and Orr as well as ourselves have found a number of toxigenic strains of *Clostridium welchii* which failed to produce "stormy fermentation" under prescribed conditions. Moreover, other nonpathogenic *Clostridia* which produce "stormy fermentation" are frequently found in wounds.

Nagler and Hayward employed methods based on the splitting of insoluble fatty material in human serum by *welchii* toxin and the specific inhibition by *welchii* antitoxin. This test done on agar plates (5) appears to be quite reliable except in the presence of *Bacillus proteus* which causes a diffuse opacity thus

interfering with the reading of the opaque zone produced around the *welchii* colony by the toxin. The necessity of employing an overnight incubation period together with special anaerobic equipment and reagents renders this method impractical for forward medical installations.

Humphreys observed that his strains of *Clostridium welchii* (50 in all) produced acrolein from glycerol. Since a wide variety of common aerobes and anaerobes did not give this reaction, he suggested that this test might be considered diagnostic for *Clostridium welchii*. Although Voisenet described a gram negative bacillus isolated from water and wine in "bitter disease" (*Bacillus amaraerylus*) which produced appreciable amounts of acrolein from glycerol, the incidence of this organism is rare and we have failed to encounter it in several hundred specimens from wounds. Thus the acrolein method as described by Humphreys may still be considered diagnostic for *Clostridium welchii* in cultures of wound specimens.

The production of acrolein from glycerol has been used in our laboratory as the basis for a rapid test for *Clostridium welchii*. This procedure depends upon: (1) the aerobic growth of anaerobes in a specially prepared medium; (2) the development of acidity which determines the testing time for acrolein; and (3) the testing for acrolein in the culture medium with a standardized Schiff's reagent. It is believed that this method is sufficiently simple and of short enough incubation period to be of value in forward medical installations. Since penicillin therapy is extensively used at present in gas gangrene, the procedure was appli-

From the First Medical General Laboratory, United States Army.

fied to include a means of determining the penicillin sensitivity of *Clostridium welchii* in mixed cultures and debrided tissue. The inhibition of acrolein by the penicillin in the medium was taken as a measure of penicillin sensitivity.

METHODS

The methods of preparing the medium and reagents and the procedure for the detection of traces of acrolein, the production of which is specific for *Clostridium welchii*, are given in detail in the following:

A. Medium.

1. Mix distilled water . . . 970 milliliters
Glycerine . . . 30 milliliters
Tryptone (Bacto) . . . 20 grams
Sodium chloride (C.P.) . . . 5 grams
Agar . . . 2 grams
2. Heat to boiling until fully dissolved.
3. Add 5 grams ascorbic acid (C.P.)
4. Adjust to pH 6.8 with 5N NaOH (about 5.0 to 5.3 ml. is required)
5. Add 7.5 milliliters of brom cresol purple solution, prepared as follows:
Distilled water . . . 99 milliliters
N/10 NaOH . . . 1 milliliter
Brom cresol purple . . . 100 milligrams
6. Dispense measured volumes (100 ml.) in screw capped bottles, fill almost completely so as to give the smallest surface exposure to air.
7. Sterilize in Arnold for 30 minutes on 2 successive days.
8. Final pH should be approximately 6.8
Final Eh should be approximately -0.150 volt.
9. Add enough penicillin aseptically to some of the bottles of medium to make 1 Oxford unit per milliliter. No depreciation of penicillin potency in the medium has been observed for at least 2 weeks when it is stored in a tightly screw-capped bottle and refrigerated.
10. The medium with or without penicillin should be stored at about 5 degrees C.

B. Modified Schiff's reagent.

The smallest amounts of acrolein produced by *Clostridium welchii* in the glycerol medium were detected by a modified Schiff's reagent. In order to obtain consistent and reproducible results, it was necessary to standardize each batch of stock reagent against known concentrations of an aldehyde. Satisfactory results

were obtained with reagents that gave a negative test (yellow color) with formaldehyde solution (U.S.P.) diluted 1:250,000 with the medium described; a faint positive test (light pink color) with formaldehyde at 1:125,000 dilution, and a strongly positive test (deep pink color) with formaldehyde diluted 1:75,000.

The stock unstandardized solution of Schiff's reagent remained stable for a month when stored in a glass stoppered brown bottle at room temperature in the dark. This solution was prepared as follows:

0.25 gram of basic fuchsin was dissolved (by heating if necessary) in 100 milliliters of distilled water and cooled to room temperature. Small insoluble residues were discarded. Fifty milliliters of freshly prepared 4 per cent sodium sulfite and 4 milliliters of concentrated hydrochloric acid were added immediately. Distilled water was added to a total volume of 250 milliliters. After standing 5 minutes at room temperature, the solution was filtered rapidly through a large fluted filter paper.

Sensitivity of the stock solution could be affected by varying the concentration of basic fuchsin or sodium sulfite. The most satisfactory standardized solutions were obtained by determining the amount of concentrated H_2SO_4 necessary to be added to stock solution to give the reactions mentioned above with the given concentrations of formaldehyde in medium. The requisite amount of sulfuric acid was determined for each batch of unstandardized reagent. Standardized stock solution was found to be unstable. It was necessary to add the required amount of concentrated H_2SO_4 to stock solution sufficient only for the tests at hand.

The titration method employed for the standardization of stock reagent was as follows:

The formaldehyde-media solutions were made by the usual methods of serial dilution. One milliliter of formalin (37-40% formaldehyde U.S.P.) was pipetted into 9 milliliters of medium and thoroughly mixed. One milliliter of this solution was pipetted into 9 milliliters of medium etc. Dilutions of 1:30,000, 1:50,000, and 1:100,000 of formalin in medium were chosen. These dilutions of formalin correspond to formaldehyde concentrations of approximately 1:75,000, 1:125,000, and 1:250,000, respectively.

To adjust the stock solutions to optimum sensitivity for tests, 0.075 milliliter of concentrated H_2SO_4 was added to a 10 milliliter portion of the stock solution of Schiff's reagent. One milliliter of this acidified reagent was added to 1 milliliter of each of the formaldehyde-medium dilutions and allowed to stand for 20 minutes. If this amount of sulfuric acid produced the optimum sensitivity, the 1:350,000 formaldehyde-medium dilution remained negative (yellow color); the 1:125,000 formaldehyde dilution

Pure cultures	27	27	27	0	4	6	6	None

¹Mixed cultures were secondary transplants of wound tissue cultures. Pure cultures of *Clostridium welchii* were isolated from tissue cultures and sent to laboratory for confirmation. Tissues were debrided tissue from wounds.

²Nagler test: Toxicogenic *Clostridium welchii* produce marked zones of opacity around colony on 20 per cent human serum proteose No. 3 (Bacto) agar plates which do not appear when *welchii* antitoxin is present.

³After Reed and Orr, based on cultural and biochemical characteristics.

⁴Combinations of 2, 3, or 4 other aerobes and anaerobes found in mixed cultures and tissue cultures.

⁵45 of the mixed cultures were negative for *Clostridium welchii* by all tests indicated in Table I.

became pale pink, and the 1:75,000 dilution became deep pink in 20 minutes. If the 1:250,000 formaldehyde tube turned pink in 20 minutes, the reagent was too sensitive and a new trial was made using more concentrated sulfuric acid (e.g. 0.1 ml.) in 10 milliliters of stock reagent. If both the 1:250,000 dilution and the 1:25,000 dilution remained yellow, the reagent was not sensitive enough, and a smaller amount of sulfuric acid was tried (0.05 ml. conc. H₂SO₄ to 10 ml. of stock solution).

C. Procedure for identifying *Clostridium welchii* and determining its sensitivity to penicillin.

1. Two milliliter portions of the medium, with or without penicillin, were pipetted into sterile Wassermann tubes just before use. Two tubes were used for each specimen. Tube 1 contained the plain medium, tube 2 contained the medium with 1 Oxford unit of penicillin per milliliter. A control tube was included with each batch of tests. This consisted of uninoculated medium which was used in order to check the sensitivity of the standardized reagent used in the test.

2. Tubes 1 and 2 were inoculated with approximately the same amounts of inoculum and mixed carefully without introducing bubbles. The inoculum consisted of 5 to 10 milli-

¹4 of the tissue cultures were negative for *Clostridium welchii* by all tests indicated in Table I.

²Includes 4 doubtful results due to presence of *Bacillus proteus* which produced diffuse opacities over entire plates.

³Organisms identified by routine cultural methods were: *Staphylococcus albus* and aureus; *Streptococcus hemolyticus*, also viridans and nonhemolytic varieties; *Bacillus proteus*; *Bacillus subtilis*; *Escherichia coli*; *Aerobacter aerogenes*; *Klebsiella friedlanderi*; diphtheroids; *Clostridium sporogenes*, *bifermentans*, *aerofetidum*, *tephanomorphum*, unidentified nonpathogenic clostridia, *oedematis*, *septicum*, *histolyticum*, *sordellii*, *tetani*.

meter pieces of freshly excised tissue, blotted free of blood, or 0.1 milliliter of mixed or pure freshly grown culture.

3. Tubes 1, 2, and the blank control were incubated *aerobically* at 37 degrees C. and observed at hourly intervals until sufficient growth had occurred to produce an acid reaction. The time for testing for acrolein was determined by the development of a decided yellow color in tube 1. This averaged 4 to 6 hours.

4. Following the necessary period of incubation, the tubes were centrifuged at 2500 revolutions per minute for 5 minutes. One milliliter of supernatant liquid was decanted from each tube into clean sterile tubes and labelled. One milliliter of "standardized" Schiff's reagent was added to each tube and mixed well. The tubes were shaken occasionally and observed for development of pink to purple color at the end of 20 minutes.

RESULTS

Clostridium welchii were identified in mixed cultures, pure cultures, and tissue by: (a) the acrolein test described herein, (b) the Nagler

TABLE II.—RESULTS AND INTERPRETATION OF THE ACROLEIN TEST FOR *CLOSTRIDIUM WELCHII* AND ITS SENSITIVITY TO PENICILLIN

Tube No	Type of supernatant		Color ¹ reaction with Schiff's reagent	Interpretation		
	Media	Inoculum		Presence of <i>Clostridium welchii</i>	Sensitivity to penicillin	Remarks
Control	Plain	None	Pink to purple			Reagent must be re-standardized and test repeated
			Yellow			Reagent satisfactory
1	Plain	Pure culture or mixed culture or tissue	Pink to purple	Present		
			Yellow	Absent		
2	1 Oxford unit of Penicillin per 1 ml of plain medium	Pure culture or mixed culture or tissue	Yellow	Present	Sensitive	
		Pure culture	Pink to purple	Present	Resistant	(Provided that Tube 1 is pink to purple)
		Mixed culture or tissue	Pink to purple	Present	Undetermined ²	

¹The presence of any shade of color from pink to purple is regarded as a positive test for acrolein, provided that the uninoculated control remains yellow during the prescribed 30 minutes

²*Clostridium welchii* may be resistant to penicillin or it may be sensitive. In the latter instance the positive acrolein reaction may be due to destruction of penicillin by other organisms present. Actual sensitivity must be determined in the above test with a pure culture.

test, and (c) routine cultural methods, as shown in Table I. All cultures of specimens which were found to contain *Clostridium welchii* by the Nagler test and the routine cultural methods gave a positive test for acrolein in the glycerol media, after approximately 4 hours' incubation. Cultures that proved to be negative for *Clostridium welchii* by the Nagler test and the routine cultural methods failed to produce acrolein in glycerol media after 24 hours' incubation. In glycerol medium containing 1 Oxford unit of penicillin per milliliter, 95 of the 102 cultures containing *Clostridium welchii* gave a negative test for acrolein. In order to correlate the inhibition of acrolein production with penicillin sensitivity, 10 pure cultures of *Clostridium welchii* obtained from the group of 95 were also tested by the filter paper disc method of Vincent and Vincent. The results obtained from these tests showed that the growth of all strains of *welchii* tested were inhibited by the penicillin in blood agar plates. It would appear that inhibition of acrolein production could be used as an indicator of the penicillin sensitivity of *Clostridium welchii*.

Seven of the remaining mixed cultures when tested in glycerol medium containing penicillin gave a positive reaction for acrolein. However, when the pure cultures of *Clostridium welchii* from these seven mixtures were

likewise tested, they gave a negative reaction for acrolein. Furthermore these pure cultures were inhibited by 1 Oxford unit of penicillin per milliliter of blood agar (filter paper disc method of Vincent and Vincent). This positive reaction for acrolein in the mixed cultures might be explained by the presence of *Escherichia coli* or *Bacillus subtilis* either alone or in combination (See Table I). These organisms have been described as penicillinase producers by Ungar and Bondi and Dietz (2, 3). While we did not test for the production of penicillinase *per se*, these results would indicate that such substances were produced in the mixtures, destroying the penicillin in the medium and thus permitting the *Clostridium welchii* to proliferate and split the glycerine to acrolein. The inactivation of penicillin in mixed cultures by nonpathogens suggests that a similar action may occur at the wound site if contaminated with the same type of bacterial flora. It should be noted however that over 93 per cent of the mixed cultures containing *Clostridium welchii* in penicillin medium gave a negative reaction for acrolein, indicating that most of the nonpathogens encountered were probably nonpenicillinase producers.

The degree of penicillin sensitivity was further demonstrated by the following method. A pure culture of *Clostridium welchii* in chopped meat broth or Brewer's thioglycol-

late medium was tested in the same manner. As a control, the filter paper disc method of Vincent and Vincent was run. Freshly grown cultures were inoculated into portions of medium containing serial dilutions of penicillin so that the final concentrations of drug were 1 Oxford unit, 0.5, 0.25, 0.125, 0.06, 0.03, 0.015 unit per milliliter of medium. Final concentration of inoculum was 1:100. A tube of medium without penicillin was also inoculated with the same amount of culture. An uninoculated blank control was run as part of the test. All the tubes were incubated and tested for acrolein as soon as the plain medium culture had turned deep yellow. The incubation period was usually about 5 hours. The smallest concentration of penicillin which inhibited the formation of acrolein was considered as an indicator of the degree of sensitivity of the test organism to penicillin.

Tests of 10 strains of *Clostridium welchii* for relative sensitivity to penicillin by the method described showed that 1 strain was sensitive to 0.03 unit of penicillin, 3 strains were sensitive to 0.06 unit, 3 strains were sensitive to 0.12 unit, 2 strains were sensitive to 0.25 unit, and 1 strain was sensitive to 0.5 unit of penicillin. Two of the strains tested (sensitive to 0.06 unit and 0.25 unit, respectively) were retested on two other occasions with the same results. Since an extensive

series of tests have not been carried out yet, no attempt has been made to estimate the limits of experimental error in this technique.

Interpretation of the results of the test given is contained in Table II.

SUMMARY

1. A method is described for the identification of *Clostridium welchii* in mixed cultures, pure cultures, and wound débridement which requires no anaerobic apparatus and is completed in an average of 4 to 6 hours.

2. The test depends on the production of acrolein which in this case is considered diagnostic for *Clostridium welchii*.

3. A procedure is also given for determining the penicillin sensitivity of *Clostridium welchii* in the above types of cultures.

REPAIR OF VESICOVAGINAL FISTULA CAUSED BY RADIATION.

GRAY H. TWOMBLY, M.D., and VICTOR F. MARSHALL, M.D., F.A.C.S.,
New York, New York

THE cure of vesicovaginal fistulas has always excited the ingenuity and taxed the skill of the surgeon. Within this class of cases, those fistulas which are the result of radiation therapy, usually to the cervix or uterus, constitute a peculiarly difficult problem. There are several reasons for this:

First, the blood supply of the tissues locally is precarious as a result of the vascular radiation damage. Indeed, this is the main underlying cause of the fistula. Further, trauma may well produce more sloughing and any effort by the surgeon to correct the condition may end in a larger fistula and more fibrosis. Even if no actual slough occurs, healing of heavily radiated tissues is notoriously uncertain.

Second, such excessively fibrosed tissues are usually quite inelastic. This fibrosis extends for a few centimeters, at least, from the opening proper, and very often the whole area is massively affected. In methods where coaptation of the fistula edges is necessary, a recognized *sine qua non* to success is the absence of tension. Coaptation is difficult in the postradiation case and may be impossible.

Third, the fibrosis itself makes dissection very difficult, particularly if it is desired to raise several flaps for a multilayer closure. Postradiation fistulas often have very thin but very tough edges.

Fourth, one, or both, of the ureteral orifices are frequently within the fistula margin. In our cases, the left ureteral orifice was within the fistula wall in every one, and the right orifice always very near it. In such instances, to raise flaps or cut off the inner edge of the fistula would cut off at least one ureter and necessitate reimplantation of one or both ureters into a new portion of the bladder—a procedure adding greatly to the difficulty and length of the operation. Furthermore, after

heavy radiation fibrosis (and its associated infection) it may be nearly impossible to dissect up the ureter for reimplantation (as in our Case 2).

Our 3 patients all had vesicovaginal fistulas as the result of therapy for cervical cancer. All were heavily radiated with both radium and x-ray. In each instance, the upper vagina and parametrial tissues were tough and inelastic, like heavy leather. The fistula margins were thin and fibrous. One patient had been seen by various consultants for 8 years all of whom had agreed that no method of closure could succeed for the reasons just enumerated.

DESCRIPTION OF OPERATION

Through a suprapubic incision, the space of Retzius is entered. The bladder is identified and, after the peritoneum has been pushed upward off the dome, a liberal cystotomy is carried out in the higher portions of the exposed bladder wall. The high position is chosen so that at closure the cystotomy catheter will be placed away from the symphysis, at a distance from the urethra and also from the site of the fistula repair. Closure at the desired later time occurs more rapidly with a high cystostomy than with one placed low. The interior of the bladder is exposed by retractors, and the fistula is inspected from above. Ureteral catheters are inserted since, by knowing exactly where the ureteral orifices are, damage to them can be completely avoided throughout remainder of the operation. The only sutures used in their vicinity are placed there under direct vision.

One of the assistants puts his finger in the rectum and pushes the posterior vaginal mucosa up against the fistula. A long handled scalpel with a small blade is used to mark out, transvesically, the pattern of posterior vaginal mucosa corresponding to the size, shape, and location of the fistula opening. The

Fig. 1. Appearance through the suprapubic cystostomy.

ureteral catheters are left in place and sterile drapes are placed over the suprapubic wound.

The patient is now arranged in the lithotomy position and the vagina and perineum are prepared and draped. The interior of the vagina is exposed and the upper third is denuded of its mucosa by sharp dissection except that the previously outlined patch on the posterior vaginal wall is left undisturbed. Moderate bleeding is encountered, but with the exception of a few easily identified larger vessels which are ligated with plain catgut, bleeding usually ceases spontaneously, or after brief packing. The posterior third of the vagina to a point about 2 centimeters in front of the fistula is now a raw surface except the previously noted patch. The external edges of this excision are sutured together with interrupted chromic catgut transversely (parallel with the operating room floor), the anterior vaginal mucosa being sutured to the posterior mucosa at the margin of the dissection. Interrupted sutures are used so that some drainage may occur between the sutures from the fairly large raw surfaces above. No drain or vaginal packing is used.

The patient is then returned to the original dorsal position. With a long needle holder and long toothed forceps, interrupted chromic catgut sutures are placed at 1 centimeter intervals through the full thickness of the fistula margin about 0.5 centimeter from the actual edge of the opening and through the edge of

Fig. 2. Sagittal section showing how the posterior vaginal wall is pushed up against the fistula.

the posterior vaginal wall patch. Four to six such sutures are usually required. At the posterior edge of the opening, there is usually a small area not requiring sutures because that edge of the patch is usually continuous with the fistula edge without any pocket intervening. If such a pocket were present, the suturing would be continued all around. During this suturing, the ureteral orifices are always in complete view, and care is taken not to place sutures too close to them. These sutures are tied just tight enough to make the patch and fistula edges touch because anything more than this might injure blood supply and allow cutting through of the sutures. In this manner, the patch is accurately fitted in place to form a floor to the fistula which is only barely depressed below the general level of the bladder base.

The cystostomy is closed with a continuous plain catgut suture through all layers of the bladder wall. This suture line is then inverted with interrupted chromic catgut mattress sutures through the outer layers of the wall. A mushroom type catheter, No. 22 to 28 size, French, is placed in the highest portion of the incision. Just above the site of the catheter, a chromic catgut suture is passed through the bladder wall, avoiding the mucosa, and each end is then put through the recti and fascia at a slightly higher level. When this suspending suture is tied, during the closure of the abdominal wall, the cystostomy site is thus held

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 3. Vaginal view after patch has been outlined from above.

Fig. 5. Transverse closure of external margins of excision. Patch still in place. (Actually the excision of vaginal mucosa is somewhat more extensive than illustrated.)

high and against the recti. Also, some bulwark is created to hold the peritoneum away from this newly formed fistula tract. The wound is closed in routine fashion and the catheter is securely fastened to the skin with adhesive.

Upon return to bed, the patient is kept abdomen down as long as she will tolerate it, up to 10 days. The suprapubic tube is very gently irrigated with solution G¹ twice daily, or more often if necessary, to insure its patency—solution G decreases precipitation of urinary salts in the tube or in the suture line. Under no circumstances is this tube closed even for a short while. The addition of low pressure, "bubble", suction is, we believe, an advantage. If the patient cannot tolerate the prone position, the "bubble" suction is probably adequate if cared for. This low pressure suction is continued for over 2 weeks after operation and the patient is then placed on straight drainage for 2 days. After this, the tube is removed and voiding usually begins in a few hours. After the suprapubic area has been dry for 24 hours, the patient is discharged. During the convalescence, a daily gentle flush of the vaginal vestibule is done with a mild antiseptic. Care is taken to introduce nothing against the vaginal suture line which might

separate it. The catgut vaginal sutures, also those in bladder, come out spontaneously.

We hope that it is readily apparent from the description given that there are two suture lines plus an adhering area of raw surfaces at least 2 centimeters wide closing the fistula. The safety from damage to the ureters should be stressed. Adequate bladder drainage without a urethral catheter is of great importance, particularly during the healing period. In our cases, the uterus and cervix already were either removed or obliterated by radiation but, if there were any question of continued uterine function, a hysterectomy would be necessary before this operation could be done.

CASE REPORTS

CASE I. Mrs. A. P. No 70622. This 34 year old female first entered Memorial Hospital on May 26, 1943, with cancer of the cervix classified as League of Nations, stage II, because it extended into the left parametrium a short distance. It was freely movable, however. A biopsy showed epidermoid carcinoma, grade II.

The patient was treated by what was the routine treatment for cancer of the cervix at that time. This consisted of roentgen therapy, 250 r to a large 14 by 19 centimeter anterior port the first day, a similar treatment to a 14 by 19 centimeter posterior port the second day, and two treatments of 250 r each to 14 by 11 centimeter right and left lateral ports the third day. The cycle was repeated until each port had received 1750 r. The factors were 200 kilovolts, peak;

¹ Citric acid (monohydrate)
Magnesium oxide (anhydrous)
Sodium carbonate (anhydrous)
Distilled water ad

32.3 gm.
3.8 gm.
4.4 gm.
1000 c.c. (to)

0.5 millimeter copper filter, 70 centimeter target skin distance, 30 milliamperes. On conclusion of the external roentgen therapy, treatment was given to the cervix through vaginal cones. This consisted of 4 treatments of 500 r each through a 4 centimeter cone to the cervix direct and 4 treatments of 750 r each to each fornix through 3.5 centimeter cones. One treatment was given daily. The factors were 130 kilovolts, peak; 0.25 millimeter brass filtration, and 35 centimeter target skin distance, 5 milliamperes.

Twelve days after this treatment was finished, a 6 centimeter plastic applicator containing 104 millicuries of radon was inserted into the cervix for a dose of 3600 millicuries hours. The filtration was 0.5 millimeter platinum plus the wall thickness (1 mm.) of the plastic applicator. Unfortunately, this was not sufficient to control the cancer, for 2 months after the insertion of the radium persistence or recurrence was noted and confirmed by biopsy.

On October 22, 1943, a "stem and base" radium applicator was applied for 1000 millicuries hours, all the radon being in the base. Also, a single capsule was packed into left vault for 750 millicuries hours.

In spite of this treatment, a biopsy on January 3, 1944, showed active cancer. The cervix was still somewhat movable and the parametria were still not widely invaded with carcinoma. On February 4, 1944, a radical Wertheim hysterectomy was done. Operation was rendered difficult by the edema and fibrosis in the bases of both broad ligaments and between the trigone and vagina. Great care was taken to cause as little trauma as possible to the base of the bladder.

Postoperatively, a pack of zinc peroxide was placed daily against the suture line closing the vagina. In spite of this care, the upper vagina parted and a large cavity lined with necrotic tissue appeared in the area previously occupied by the uterus. The cavity slowly cleaned up and decreased in size, but the base of the bladder remained white. A small rectovaginal fistula appeared and then healed spontaneously. Two months after the radical hysterectomy, the white area in the bladder trigone separated, and the patient developed a large vesicovaginal fistula. It was so large that the index finger could be introduced with ease into the bladder through it.

The fistula was observed at frequent intervals from then on and various plans devised to try to diminish the leakage. A rubber condom was packed with cotton and inserted daily by the patient to try to stop the leak mechanically. This did not help. A contraceptive pessary was fitted to try to occlude the opening, again without improvement.

Thirteen months after the radical hysterectomy and 11 months after development of the vesicovaginal fistula, after three biopsies from the edge of the fistula had shown no carcinoma, the above described operation was carried out on March 1, 1945. The patient was kept flat on her abdomen in bed for 2 weeks, then gradually allowed to resume normal activities. A little urine leaked from the

Fig. 6. Cystotomy view showing fistula edges sutured to patch.

vagina postoperatively on one or two occasions when the suprapubic tube was kinked or plugged.

She was discharged from the hospital 3 weeks after operation and has remained dry and free of any evidence of cancer since (8 months). Urinary control is normal. The result of the operation was a matter of intense joy and satisfaction to the patient. Repeated cystoscopic examinations clearly showed the patch of vaginal mucosa and on two occasions, thin, friable, white concretions were seen on its surface and scraped away with biopsy rongeurs.

The patient has had repeated sexual intercourse since her operation and, in spite of the shortening of the vagina which measures little more than 5 centimeters in length, reports satisfaction both to herself and husband after some adjustment.

Intravenous pyelograms made before the radical hysterectomy showed no hydronephrosis. After operation, they showed considerable hydronephrosis, most marked on the right side. This gradually diminished over the next month. Unfortunately no pyelogram was made immediately before the plastic closure of the fistula, but a recent intravenous pyelogram 8 months after this operation shows normal kidney function and no dilatation of the ureters.

CASE 2. Mrs. E. B. No. 52286. This 31 year old patient first entered Memorial Hospital on September 17, 1936, complaining of a foul-smelling, watery vaginal discharge first noticed 6 months previously during her third pregnancy. Examination revealed a large fungating carcinoma of the cervix, graded II on biopsy. It did not extend into the parametria and was classified as League of Nations stage I.

She was treated with external roentgen therapy to six 10 by 14 centimeters pelvic ports from September 21, 1936, to October 10, 1936, each port receiving first 100 r, then 150 r, 200 r, 250 r, 300 r and 350 r, for 1350 r per port. The factors were 200 kilovolt peak, 0.5 millimeter copper filter, 70 centimeter target skin distance, and 30 milliamperes. On October 26,

Fig. 7 Sagittal section showing end result. (Cystostomy tube not illustrated.)

radium in a vaginal applicator (bomb) was placed against the cervix for 1500 millicuries hours. The next day a radium tandem was inserted into the cervical canal for 3000 millicuries hours. The filtration of both of these applicators was the equivalent of 0.5 millimeter of platinum.

On subsequent follow-up visits, it was noted that fluid accumulated inside the uterine cavity which gradually became purulent and foul. Dilatation of the cervix failed to provide adequate drainage and she became chronically ill by the prolonged sepsis.

Finally, as a palliative procedure on February 27, 1937, 4 months after radium treatment, a supra-cervical hysterectomy was performed, the dilated fundus which by then was a very foul sac of pus, being removed. During the operation, an attempt was made to dissect the base of the bladder off the cervix but this was abandoned because of the edema and fibrosis encountered. Most of the cervix was left *in situ*, a cigarette drain being passed down through its center into the vagina. No cancer was found in the operative specimen.

Postoperatively, a large abscess formed in the posterior cul-de-sac which began to discharge through the cervix a month after operation.

In May, 1937, she was hospitalized elsewhere because of acute abdominal pain, dysuria, and gross hematuria. While there, she had an acute vaginal hemorrhage and developed both rectovaginal and vesicovaginal fistulas. From then on, her general condition began to improve greatly so that in November, 1937, it was noted she looked well and had no complaint save for constant leakage of urine.

She was seen at frequent intervals in the follow-up clinic without developing any sign of recurrence of the cancer. Save for occasional bouts of cystitis, with some bleeding at times, she remained well. Frequent consultations were held as to the possibility of closing the fistulas, but it was generally agreed that any procedure toward this end was not feasible.

Finally in September, 1945, 8 years after the fistulas developed and after we had seen the success which attended the operative treatment of our first

case, she was admitted again with the hope of performing a similar procedure.

Examination showed as in the first case a fistula on the anterior wall of the vagina at its apex through which the tip of the index finger could be inserted into the bladder. Introduction of methylene blue into the rectum showed it to pour out through the same opening. A barium enema done under fluoroscopic guidance with a thin barium solution showed this fistulous opening communicating with the mid-sigmoid. Intravenous pyelograms demonstrated a left hydronephrosis and hydroureter.

On September 13, 1945, the patient was operated upon as here described. Two observations should be made on this procedure; first, that it was necessary to open the abdomen and disconnect the sigmoid from the base of the bladder. The fistulous tract was turned in and closed by three layers of sutures in the wall of the bowel. The bladder defect could not be so treated because of the extensive fibrosis and consequently it was closed with interrupted sutures placed on the posterior side (i.e. in the cul de-sac). The cervix was not seen.

The second point of note was that there was hydroureter of the left ureter which emptied through a tiny opening into the left lateral wall of the fistula. This opening could not be dilated sufficiently to allow the introduction of a fine probe or of a ureteral catheter and consequently only the right ureter was catheterized. An attempt was made to dissect the left ureter free and reimplant it in the bladder. There was such marked radiation fibrosis of the ureter all along its course in the pelvis that it could not be separated safely, and the attempt was abandoned.

The patient was kept on her abdomen for 8 days after operation. When she was allowed to turn on her back after that time, urine began to leak through the vagina. Finally with the help of constant gentle suction on the suprapubic cystostomy tube, she was kept dry and healed solidly. A brief febrile episode, due to left pyelonephritis, cleared with penicillin therapy. She was discharged from the hospital on the thirty-eighth postoperative day.

Since then she has remained well and completely dry with normal control of urine. The vagina is 6 centimeters deep and completely healed. Cystoscopic examination shows the patch to be covered by a small amount of white, easily removed exudate. Intravenous pyelogram shows no change compared with the examination before operation. The patient has had sexual intercourse since operation.

CASE 3. M. C. No. 72338. This 45 year old patient first entered Memorial Hospital on November 26, 1933, with cancer of the cervix classified as League of Nations, stage III, because it extended in the left parametrium to the pelvic wall with fixation on that side.

She had been treated at another hospital on March 21, 1943, with 2000 millicuries hours of radium in 2 capsules inserted into the cervical canal. This was repeated on May 9. In October, vaginal bleeding recurred and at the same hospital on October 24,

2000 millicuries hours of radium was administered for the third time.

Since a biopsy on admission to Memorial Hospital showed epidermoid carcinoma, grade II, roentgen therapy was begun on December 3 and continued until January 4, during which time each of six r_4 by 11 centimeters pelvic ports received 250 r times 8, or 2000 r. The factors were 200 kilovolt peak, 0.5 millimeter copper filter, 70 centimeter target skin distance, and 30 milliamperes. On January 13, 1944, a vaginal bomb was placed against the cervix for 1500 millicuries hours. On January 14, a radium tandem was inserted into the cervical canal for 3000 millicuries hours.

Three months later it was noted that the cervix had been replaced by a large crater filled with foul-smelling slough.

On January 31, 1945, a year after her last radium treatment, a large vesicovaginal fistula at the upper end of the vagina was seen but all evidence of cancer had disappeared save for thickening and scarring in the left parametrium. She complained of complete urinary incontinence. Biopsies from the edge of the fistula showed no evidence of cancer.

Consequently, on September 27, 1945, a year and 9 months after the last radium treatment, the fistula was repaired by the technique already described. The left ureter, as in the other 2 cases, was found opening into the margin of the defect, but no evidence of hydronephrosis or hydroureter could be demonstrated by intravenous pyelography preoperatively. The operation was somewhat easier than those in the other 2 cases because the tissues of the bladder and vagina were more elastic and had a better circulation. The uterus was still present. A hysterectomy had not preceded the fistula repair but the uterine canal and cervix had been completely destroyed by the radium she had received.

Postoperative convalescence was uneventful and no urine came from the vagina at any time. She was allowed out of bed on the fifteenth postoperative day. The suprapubic catheter was removed on the seventeenth day. She was discharged dry, with complete urinary control on the twenty-third day after operation.

A month and a half later, cystoscopy showed the patch of vaginal mucosa in the base of the bladder to be clean, pale and not inflamed. The vagina was about 4 centimeters in length and the patient reported that she had had sexual relations satisfactorily without discomfort. Intravenous pyelograms showed that both kidneys excreted the dye at 5 minutes. There was no evidence of obstruction in either ureter. There were still some thickening and scarring felt by rectum in the base of the left broad ligament, but the clinical opinion was that this represented radiation fibrosis and not recurrent cancer.

DISCUSSION

This method of closure was devised without reference to published articles on the subject

Fig. 8. Diagram of low pressure, "bubble," suction drainage.

but, as commonly happens, we now find that many of its individual features have been used and described before. However, the plan of attack as a whole seems original. Such time-honored principles as lack of tension, preservation of blood supply, separated suture lines and a wide area of coated raw surfaces are included. The operation of colpocleisis; partial or total, is old but is at times still advised (1, 2, 3, 4, 5, 6). It was devised first by Gustav Simon, of Darmstadt, in 1855 and later by Dr. Nathan Bozeman, of New York. Simon's operation of colpocleisis left the uterus emptying into the bladder and also left a dependent diverticulum in the bladder floor. Cystitis and calculus formation were common sequelae. Latzko improved this operation and incidence of these sequelae are less in his hands.

Our operation does not leave the uterus emptying into the bladder at all since the uterus has been removed or destroyed by radium, nor does a diverticulum result. Thus far no calculi have formed, the patients have not been troubled with cystitis symptoms after the immediate postoperative period, and repeated cystoscopic check-ups have found a steady diminution in the inflammatory re-

action about the patch site. Complete obliteration of the vagina may be necessary rarely but has the objection of excluding normal sexual activity—not uncommonly an important item with these patients. The partial obliteration resulting from our procedure has in each instance left a vagina of 4 to 6 centimeters in length and all patients have had sexual relations since operation, though some adjustment was necessary.

The idea of using a patch of tissue from the posterior vaginal wall is also by no means new. Trendelenburg, in 1890, described a two stage operation on the pedicle graft principle to transfer a patch from the posterior vaginal wall to cover the fistula in the anterior wall. J. R. Miller in the discussion of another paper mentioned a case with a "blowout patch" of vaginal mucous membrane closing the fistula. This operation by Miller was very nearly like ours but apparently the suprapubic approach was not used. Witzel described the use of a patch of mucosa from the posterior vaginal wall sewed into the fistulous opening but did not accompany this by partial colpocleisis. The suprapubic approach has been described and perfected many times since Trendelenburg first advocated it in 1890. Catheterization of the ureters during operation is, of course, not original. In this connection, it might be well to remember that the only patient operated upon in London by the famous J. Marion Sims died because the ureters were included in the sutures (8). Various methods, including cystostomy, have been used to provide adequate drainage postoperatively. The indwelling urethral catheter rests on the newly repaired area and always sets up some urethral inflammation, but a well placed and cared for cystostomy tube does neither of these. Many plans for constant emptying of the bladder have been devised but the prone position and the low pressure, "bubble" suction seem the most efficient to us. The continuous prone position becomes a hardship to the patient and may allow the suprapubic tube to kink without the nurse's knowledge. However, it is simple and to the point. Low pressure suction is more comfortable but the apparatus requires constant attention and

does not prevent slight leakage through the repaired area, particularly for the most important first few postoperative days.

SUMMARY

Repair of vesicovaginal fistulas in heavily irradiated tissues is peculiarly difficult because the local blood supply is precarious, the tissues are inelastic and fixed, and the tissues are so fibrotic as to make dissection, particularly of flaps, quite difficult. Also the frequent intimate association of the ureteral orifices adds to the problem greatly.

The plan described is to be used only where residual cancer is ruled out, where the uterus and cervix are removed, or clearly obliterated, and where the urinary status after fistula closure would be expected to be satisfactory (especially good sphincter control). Sexual activity after operation is possible.

The operation is a combined transvesical and vaginal approach which permits complete safety to the ureteral orifices in or near the opening; a two suture line closure with these lines separated by at least a 2 centimeter adhering area of raw surfaces; a minimum damage to blood supply; closure without tension; relatively simple and easy dissection; and adequate bladder drainage during the postoperative period without a foreign body irritating the newly repaired area.

Postoperative care is directed toward continuous gentle bladder drainage and cleanliness of the wounds.

Only 3 cases are reported but the successful result in each, considering the unfavorable preoperative condition, seems to indicate the value of the method.

MANDIBULAR TUMORS

A Clinical, Roentgenographic, and Histopathologic Study

LOUIS T. BYARS, M.D., F.A.C.S., St. Louis, Missouri, and BERNARD G. SARNAT, M.D., Chicago, Illinois

THE diagnosis of ameloblastoma (adamantinoma) of the mandible has been made frequently by use of only the roentgenogram. The multilocular appearance in the roentgenogram is supposed by some to be characteristic of the ameloblastomas. It is the purpose of this report to demonstrate that (1) many jaw tumors can produce a similar roentgenographic picture, and (2) ameloblastomas have not a constant characteristic roentgenographic picture. Consequently the roentgenogram alone cannot be depended upon for a diagnosis of ameloblastoma or of any other type of jaw tumor.

CASE REPORTS

The following series of 12 case reports including roentgenograms and photomicrographs has been carefully selected principally from our office and hospital files on mandibular tumors. The pertinent findings are summarized in Table I. The series has been divided into two groups.

- I. Ameloblastomas with varying roentgenographic findings.
 - A. Roentgenogram "typical" of ameloblastoma.
 - B. Roentgenogram similar to that of a dentigerous cyst.
 - C. Roentgenogram similar to that of a retained root fragment and cyst.
 - D. Roentgenogram similar to that of an invasive tumor of bone.
- II. Benign and malignant tumors (other than the ameloblastoma) which appear multilocular on the roentgenogram.
 - A. Multiple follicular cyst.
 - B. Giant cell tumor (local).
 - C. Giant cell tumor (general). Hyperparathyroidism.
 - D. Fibroma.
 - E. Fibrosarcoma.
 - F. Osteogenic sarcoma.
 - G. Metastatic carcinoma from the breast.
 - H. Metastatic carcinoma from the thyroid.

From the Department of Surgery, Division of Plastic Surgery Washington University Medical School.

Ameloblastomas with Varying Roentgenographic Findings

Roentgenogram "typical" of ameloblastoma. C.E.S., white male, aged 71 years, was first seen on October 11, 1940. Several years before, the patient noticed the left side of his jaw was enlarged. Physical examination revealed a hard nonmovable mass which extended from one centimeter below the zygomatic process to the lower border of the ramus. Intraoral examination revealed a fistula in the region of the lower left third molar. On October 12, 1940, through an intraoral incision a large cyst was removed from the left mandible at the angle. Iodoform and balsam of Peru pack was inserted. The tissue on cut section was white, fibrous, rather firm, and not characteristic. The microscopic diagnosis was ameloblastoma (Fig. 1 a).

The patient was next seen on December 2, 1941, and complained that 3 months before the jaw began to swell at the left angle again. Some pain which was not very severe was present. The patient was operated upon December 3, 1941, and because the ameloblastoma had "recurred," causing a pathological fracture of the mandible, and because the tumor was no longer contained within the mandible but invading the surrounding tissue, cautery destruction of the growth was done.

Roentgenogram similar to that of a dentigerous cyst. B.J.B., white female, aged 17 years, was first seen on February 12, 1945. Patient stated that she had a "gum boil" at the back of the left jaw for the previous 6 weeks. Physical examination revealed a soft tissue mass in the left retromolar area which was 0.5 centimeter in diameter. The mass was neither tender nor movable. There was a moderate expansion of the body of the mandible in this area. On March 8, 1945, an incision was made in the retromolar area, the mucoperiosteum was reflected laterally and the lingual nerve was preserved. An entrance was gained to the cyst cavity by removal of the thin plate of bone. There was considerable solid material which was removed completely from the cyst wall. The cavity was packed with iodoform gauze. Histopathologic diagnosis was ameloblastoma (Fig. 1 b).

Roentgenogram similar to that of a retained root fragment and cyst. F.M.A., white male, aged 40 years, was first seen March 29, 1938. Patient first noticed a lump in the right mandible about 1 centimeter in diameter, 6 weeks before while shaving. There was no pain. There had been drainage into the mouth from the region of the mass for 1 week.

TABLE I.—CHARACTERISTICS OF MANDIBULAR TUMORS WHICH APPEAR MULTILOCULAR ON THE ROENTGENOGRAM

Histopathologic diagnosis of various cases	Age when seen years	Clinical history	Clinical findings	Location in mandible	Edeutulous areas	Miscellaneous
I A Ameloblastoma See Fig 1 a	71	Several years ago left side of mandible enlarged. Discharge from molar area 6 months ago. Reoperated upon 14 months later	Hard, nonmovable mass extending from a cm below zygoma to lower border of ramus	Angle and ramus	Complete mandible	Pathologic fracture—subsequently
I B Ameloblastoma See Fig 1 b	17	"Gum boil" behind last tooth of mandible 6 weeks	0.5 cm mass, retromolar area, moderate expansion of mandible	Angle and most of ramus	None	
I C Ameloblastoma-odontoma See Figs 1 c & e	40	1 cm lump back part of mandible noticed 6 weeks previously while shaving	Firm, fixed, nontender, 5 cm mass extending from mental foramen to angle	Molar area	Involved area	
II A Multiple follicular cyst See Fig 2	43	Firm in jaw 8 months. Lower teeth extracted 7 months ago, swelling of jaw and discharge 2 weeks	Moderate enlargement of mandible from angle to cuspid area. Draining sinus molar left area	Molar area, angle, and ramus	Complete mandible	Bilateral involvement of mandible
II B Giant cell tumor (focal) See Fig 3	23	Painless, progressive swelling both sides of mandible for 6 years	Both rami of mandible enlarged and irregular	Everything posterior to locuspid area except condyle	Involved area	Blood serum calcium and phosphorus within normal limits. Bilateral involvement of mandible
II C Giant cell tumor (hyperparathyroidism) See Fig 4	40	Painful jaw 13 years, all teeth extracted 4 years ago. Four weeks ago mandible began to swell	Smooth, sharply outlined tumor which extended halfway up anterior border of ilia near angle of nose. 3 x 1 gland	Angle	Complete mandible	Preoperative Ht S Ca, 14.6 mgm % Ht S P, 4.4 mgm % Postoperative Ht S Ca, 9.4 mgm % Ht S P, 3.1 mgm %
II D Fibroma See Fig 5	15	Swelling of jaw, 4 months sharp shooting pains to ear jaw dentist stated trouble caused by erupting wisdom tooth	Firm, fixed, nontender mass in parotid region and extended to angle of jaw	Angle and ramus	None	
II E Fibrosarcoma See Fig 6	4	Intermittent toothache for 8 weeks, rapid swelling of face and mandible, 6 weeks dentist and otolaryngologist found nothing wrong Sulfamidamide prescribed	Large, hard mass which extended from lower border of ear to upper border of	Molar area and everything posterior	Involved area	
II F Osteogenic sarcoma See Fig 7	20	Swelling of mandible, months. Diagnosis of impacted wisdom tooth which not heal. Wound did	Diffuse, firm swelling at angle of jaw. Surrounding tissues indurated. Unable to open mouth	Molar area, angle and ramus	None	
II G Metastatic carcinoma from breast See Fig 8	57	Numbness and tingling of lower lip and lump in mandible 6 months. Molars in area extracted and 8 deep x-ray therapy treatments with no relief. Diagnosis of carcinoma of breast 1955	Nontender, round, hard mass, 1.5 cm in diameter in about molar region	Molar area	Involved area	
II H Metastatic carcinoma from thyroid See Fig 9	55	Dull pain in mandible 5 weeks	Resilient mass, lingual pre-stony hard diffuse enlargement of right lobe of thyroid gland	Bicuspid area	Complete mandible	Tumor also metastasized to right iliac crest

Fig. 1. Roentgenograms illustrating the various patterns which the ameloblastoma may assume: a, "typical" of an ameloblastoma; b, similar to that of a dentigerous cyst; c, similar to that of a retained root fragment and cyst (a and c from Byars and Sarnat, *Surg. Gyn. Obst.*, 1945, 81: 575); d, ameloblastoma with infiltrating characteristics (courtesy of C. V. Mosby Co., St. Louis, Mo. From Thoma, *Oral Pathology*, Fig. 937 A, 2d ed., 1944);

e, photomicrograph obtained from specimen in Case I C. Note the columnar cells arranged in a palisade formation. In the center of these areas there appears to be a clear cytoplasm, the margins of which cannot be determined because of the fine reticulum. There is a moderate amount of dense connective tissue stroma between the groups of tumor cells. Note areas of osteodentin, O. Diagnosis: ameloblastoma—odontome (Fig. 1c).

Physical examination revealed no teeth in the lower right jaw and a firmly fixed nontender mass about 5 centimeters in diameter, extending from about the mental foramen to the angle. On March 31, 1938, patient had a resection of the mandible. Surgical specimen consisted of a round, firm tumor attached to a portion of the mandible. When cut, there was a very distinctly gritty sensation to the knife. The cut surface presented a very cellular appearance. The histopathologic diagnosis was ameloblastoma and odontoma (Figs. 1 c and e).

Patient was seen in April of 1940 and there was no evidence of recurrence. In August, 1944, the patient wrote that jaw has never given him any trouble.

Roentgenogram similar to that of an invasive tumor of bone. Figure 1 d is an illustration of an ameloblastoma similar to that of an invasive tumor of bone.

complained of pain in the lower jaw since about March, 1942. In April of 1942 he had all of his lower teeth extracted. There had been a foul taste in the mouth for the previous 6 months. In early November he noticed a swelling in the left lower jaw and since that time there had been a discharge of grayish material. Physical examination revealed a fistula in the lower left molar area. On November 28, 1942, through an intraoral approach the cysts of the mandible were excised bilaterally. The cyst wall was white, thin, but firm. The inner wall of the cyst was glistening and the cyst contained fine brown, friable material. The histopathologic diagnosis was multiple follicular cyst (Fig. 2).

Giant cell tumor (local). B.A.L., white female, aged 13 years, was first seen on April 15, 1942. About 6 years before patient noticed swelling of both sides of the face unaccompanied by pain. From 1936 to 1938 patient had 8 operations on the mandible. There was no similar condition in any other member of the family. Examination revealed that both rami of the mandible were enlarged and irregular, but normal in dimension in the long axis. On July 8, 1942, there were the following laboratory findings:

Benign and Malignant Tumors (Other Than the Ameloblastoma) Which Appear Multilocular on the Roentgenogram

Multiple follicular cyst. J.W.J., white male, aged 45 years, was first seen November 27, 1942. Patient

SURGERY, GYNECOLOGY AND OBSTETRICS

Fig. 2. a, left, Lateral roentgenogram of mandible. The histopathologic diagnosis is multiple follicular cyst (Fig. 2b). b, Photomicrograph of specimen obtained from Case

II A. Note cyst wall, the lining of which is made up of stratified squamous epithelium. Diagnosis: Multiple follicular cyst (Fig. 2a). X70.

blood serum calcium, 11.7 milligrams per cent. blood serum phosphorus, 4.9 milligrams per cent. blood serum phosphatase, 9.4 Bodansky units.

On July 9, 1942, an incision was made on the left side of the neck in the fold from the side of the thyroid cartilage to the base of the ear. This flap was dissected upward exposing the right side of the mandible on the outer plate of which was a hard, raised, bluish discoloration. The outer plate was removed by chisel and a tumor mass exposed, which ran throughout the anterior two-thirds of the mandible on its right side. The tumor was removed by curettage and chisel, but due to its numerous ramifications in the bone, it was highly improbable that all the cells were removed completely. The tumor was fragmented, fairly firm yellowish-gray. The cavity in the mandible was packed with iodoform gauze led through the soft tissues to the exterior. The histopathologic diagnosis was giant cell tumor

(Fig. 3). Roentgenograms taken periodically have shown regression of the tumor area. There was no recurrence up to March, 1945.

Giant cell tumor (general), hyperparathyroidism. L. C. C., white female (general), aged 40 years, was first seen on March 26, 1941. Patient stated that she had an abdominal operation in 1928 and since that time two teeth of her jaw had been sore. Two years later came worse. About this time patient began to have attacks of vomiting which continued for 11 months when she was operated upon for a floating kidney without any subsequent relief. About a year before, patient experienced severe pain in jaw and thought something broke. Because of weakness she was suspected of having tuberculosis. Four weeks previously the right side of the jaw began to swell. Examination revealed a tumor of the right mandible which was smooth and sharply outlined and ven-

destroyed, and also bone formation. In addition note the dense collection of fibroblastic cells in which there are many multinucleated giant cells. Diagnosis: giant cell tumor of mandible (Fig. 3a). X70.

Fig. 3. a, left, Lateral roentgenogram of mandible. The histopathologic diagnosis is giant cell tumor (Fig. 3b). b, Photomicrograph of specimen obtained from Case II B. Note bone the margins of which are irregular and are being

Fig. 4. a, left, Lateral roentgenogram of the mandible. The histopathologic diagnosis is giant cell tumor. The patient had a parathyroid adenoma (Fig. 4 b). b, Photomicrograph of specimen obtained from Case II C. Note the

fibrous connective tissue which contains an enormous number of multinucleated giant cells. Diagnosis: giant cell tumor of mandible (Fig. 4 a). (Also see Table I and contrast with Case II B). $\times 125$.

halfway up on the anterior border of the ramus. There was a distinct swelling 1 centimeter wide at the level of the nose near the ala. There was a tender 3 by 1 centimeter node on the right side in the region of the thyroid gland. At laboratory examination the following findings were revealed: blood serum calcium, 14.6 milligrams per cent; blood serum phosphorus, 2.4 milligrams per cent; blood serum phosphatase, 11.8 Bodansky units.

On March 27, 1941, tumors were removed from both upper and lower jaws on the right side. Following this a parathyroid tumor was removed deep to the lower pole of the thyroid on the right. The jaw material consisted of several small pieces of irregularly shaped brownish friable tissue. The histopathologic diagnosis was giant cell tumor (Fig. 4). Laboratory findings on the seventh postoperative day revealed the following: blood serum calcium, 9.2

milligrams per cent; blood serum phosphorus, 5.1 milligrams per cent. On October 9, 1944, patient stated that she felt perfectly all right.

Fibroma. L.C.H., white female, aged 15 years, was first seen on December 1, 1944. Patient complained of swelling of the right jaw since August, 1944. At that time a dentist said that a wisdom tooth was erupting. The growth had increased in size somewhat since and there had been sharp shooting pains in the right ear, in addition to some disability in the use of the jaw. Two weeks before a physician took a roentgenogram and told her the mass was attached to the bone. Physical examination revealed a visible lump in the right parotid region. It was firm, not movable, and not tender, and extended to the angle of the jaw. There was some limitation of movement of the jaw. The teeth were in good condition.

Fig. 5. a, left, Lateral roentgenogram of the mandible. The histopathologic diagnosis is fibroma (Fig. 5 b). b, Photomicrograph of specimen obtained from Case II D.

The tumor is an acellular collagenous fibroma of bone the cell origin of which is indeterminate. Diagnosis: fibroma (Fig. 5a). $\times 125$.

Fig. 6 a, left, Lateral roentgenogram of mandible. The histopathologic diagnosis is fibrosarcoma (Fig. 6 b). b, Photomicrograph of specimen from Case II E. The tumor is extremely cellular. The individual cells are spindle

shaped to rounded, the nuclei are variable in size, shape, and staining reaction; many are hyperchromatic; numerous mitotic figures seen. This is a rapidly growing neoplasm of fibroblastic origin. Diagnosis fibrosarcoma (Fig. 6a). X125

On December 2, 1944, an incision was made from below the lobe of the right ear forward under the mandible to below the lateral incisor region. Skin, parotid and tissue superficial to submaxillary salivary gland were all turned upward to expose the angle and body of the mandible. The masseter muscle was dissected free from the ramus, exposing the entire ramus and angle which were involved by the tumor. The mandible was sectioned at the last molar tooth. The ramus was disarticulated and removed. Another half inch of bone was removed from the forward fragment because it was questionable

whether the tumor had been encroached upon at the point of section. The jaws were wired in occlusion. The surgical specimen consisted of the right ramus of the mandible which was surrounded and permeated by a firm, resilient, nonfriable white tumor mass. The specimen cut with increased resistance and showed a thin white capsule which completely surrounded the tumor mass. The cut surface of the mass was yellow with streaks of white tissue running through it. It showed some evidence of hemorrhage but no cystic changes grossly. The tumor was growing on both sides of the mandible, which was thin and showed evidence of bone destruction. The histopathologic diagnosis was fibroma (Fig. 5).

Fig. 7 a, left, Lateral roentgenogram of mandible. The histopathologic diagnosis is osteogenic sarcoma (Fig. 7 b). b, Photomicrograph of specimen obtained from Case II F. Note thick layer of fibrous tissue which is growing without any plan. The cell outlines are not sharp. The nuclei are

for the most part elongated and vary in size, shape, and staining reaction. An occasional mitotic figure is seen. In other areas abnormal bone formation is seen. Diagnosis osteogenic sarcoma from membranous bone (Fig. 7 a). X125.

Fig. 8. a, left, Lateral roentgenogram of the mandible. The histopathologic diagnosis is metastatic carcinoma from the breast (Figs. 8 b and 1 d). b, Photomicrograph of specimen obtained from Case II G.

men obtained from Case II G. Note islands of malignant undifferentiated epithelial cells. Diagnosis: carcinoma of the mandible (metastatic from the breast) (Fig. 8 a). $\times 125$.

Fibrosarcoma. H.F.G., white male, aged 4 years, was first seen on January 4, 1945. About 8 weeks before the patient suddenly began to complain of intermittent toothache in the left mandible. Patient was examined by a dentist who found nothing wrong. The patient was examined by an otolaryngologist who likewise found nothing wrong and prescribed sulfanilamide. About 6 weeks previously a mass about the size of a grape was noticed in the left jaw. This continued to grow until at the present time it involved a considerable portion of the face. Extraoral examination revealed a large, hard, moderately tender mass which extended from below the lower border of the posterior part of the mandible up to the superior border of the ear. The anterior portion of the ear was pushed outward with the mass. Intraoral examination revealed a mass arising from the

mandible behind the last molar. The mass pushed the left tonsillar area over to the midline of the pharynx. On January 6, 1945, biopsy was made on the jaw tumor. The histopathologic diagnosis was fibrosarcoma (Fig. 6).

Osteogenic sarcoma. V.M.B., white female, aged 20 years, was seen on October 16, 1940. In July, 1940, the patient stated that her jaw on the left side began to swell. Patient went to a physician who took roentgenograms and said there was an impacted wisdom tooth. Physical examination revealed a diffuse swelling at the left angle of the jaw, firm and sensitive to pressure. The surrounding tissues were indurated. Patient was unable to open her mouth.

On October 17, 1940, an incision was made on the left side of the neck and the tissues elevated from the mandible. It was found that the entire half of the

Fig. 9. a, left, Lateral roentgenogram of mandible. The histopathologic diagnosis is metastatic carcinoma from the thyroid (Fig. 9 b). b, Photomicrograph of specimen obtained from Case II H. The thyroid glandular tissue is

hyperplastic. The cells as a whole are well differentiated. Abnormal mitotic figures are not observed. Diagnosis: carcinoma of mandible (metastatic from thyroid) (Fig. 9 a). $\times 125$.

Fig. 10. Common errors made in diagnosis of jaw tumors. Presenting signs, symptoms, findings, and common misdiagnoses. *a*, Gum boil, granulation tissue, *A*, impacted molar, *B*; paresthesia and anesthesia of lip, pain in teeth

and mandible, *C*, *b*, Draining sinus, *A*; loose teeth, pyorrhea, *B* (Pyorrhea is not the only cause for loose teeth); swelling of face, *C*, *c*, Pain in ear, *A*; limitation of movement of jaw, *B*; fracture, *C*

mandible was involved with an invasive tumor. It was definitely malignant and too extensive to offer any hope of cure from a radical operation. The histopathologic diagnosis was osteogenic sarcoma (Fig. 7). Patient died on June 18, 1941.

Metastatic carcinoma from the breast. C.S.F., white female, aged 57 years, was first seen February 11, 1943. Patient complained of numbness and tingling of the lower lip since August, 1942. In addition at that time a lump was noticed in the right mandible. Patient went to a dentist who extracted the right lower molars, but there was no relief from the symptoms. She went to a physician who gave 8 deep x-ray therapy treatments. Patient had a left radical breast removal for carcinoma 1½ years previously and there had been no evidence of recurrence. Physical examination revealed a nontender, round, hard mass, 1.5 centimeters in diameter, in the right mandible at the molar region.

On February 12, 1943, in the region of the right molar, the buccal plate was removed exposing a hard tumor 3 by 2 by 2 centimeters which was removed and the bed cauterized with heat. The specimen was white, very firm and appeared to be fibrous tissue. Tissue was sent to surgical pathology for rapid frozen section. The histopathologic diagnosis was metastatic carcinoma from the breast (Fig. 8).

Metastatic carcinoma from the thyroid. E.L.W., white female, aged 55 years, was first seen on October 25, 1938. This patient complained of dull pain in the left mandible for 5 weeks. Her dentist took roentgenograms of the jaw and found destruction of bone. Patient stated that she had had a goiter for 25 years, but it had remained unchanged. Physical examination revealed that on the lingual surface of the left lower jaw in the premolar area there was a mass which extended down to the lower border of the jaw. It was palpated on the outside where it was quite painful. There was a stony hard diffuse enlargement of the right lobe of the thyroid gland.

On October 26, 1938, an opening was made into the jaw bone and a rather vascular type of tumor was removed. The microscopic report was metastatic carcinoma from the thyroid (Fig. 9). On November 2, 1938, the right lobe and the isthmus of the thyroid

gland were removed and the microscopic report was adenocarcinoma of the thyroid. Patient was again seen on June 7, 1942, complaining of pain in the right iliac crest and difficulty in walking. Two series of x-ray therapy each consisting of 2400 roentgen units were given to this area. Patient was again seen on March 31, 1943, and she stated that she had pain in the left mandible since October, 1942, and during the last few months a lump had appeared. She had had no complaints in regard to the jaw since the last operation of 1938. The mass was excised by means of cautery and found to be metastatic thyroid tissue. The tumor of the ilium was also excised and this too was found to be adenocarcinoma of the thyroid. The patient was last seen in 1945 and no evidence of carcinoma was found.

DISCUSSION

Roentgenograms of the mandible. Entirely satisfactory roentgenograms of the mandible are usually difficult to obtain. The masseter and internal pterygoid muscles, the pharynx and other soft tissue structures interfere. In addition, superposition of the other side of the mandible, the maxilla, the vertebrae, and the thyroid bone confuse the picture. Comparison of preoperative roentgenograms of the mandible with roentgenograms of the resected tumor and mandible reveal striking differences (1). The latter, devoid of surrounding tissue, show remarkably sharp. This problem is partly answered clinically by use of the laminagram.

Classification of "cystic" lesions of the mandible. Any practical clinical classification of "cystic" lesions of the mandible should be all inclusive. Many errors are made in the clinical diagnosis of jaw tumors (Fig. 10). The histopathologic diagnosis is specific. The roentgenographic diagnosis, however, is non-

specific and includes many tumors which are radiolucent but not truly cystic. Consequently, in the differential diagnosis the following should be considered on a roentgenographic basis.

TUMORS OF THE MANDIBLE

- I. Tumors of dental origin.
 - A. Follicular cyst (single and multiple).
 - B. Dentigerous cyst.
 - C. Ameloblastoma (preameloblastoma).
 - D. Radicular cyst (or granuloma).
- II. Tumors of nondental origin.
 - A. Primary in mandible.
 1. Benign—
 - a. Giant cell,
 - b. Eosinophilic granuloma,
 - c. Fibroma,
 - d. Traumatic.
 2. Malignant—
 - a. Carcinoma (local spread),
 - b. Sarcoma (fibrosarcoma, osteogenic sarcoma, Ewing's).
 - B. Secondary in mandible.
 1. Metastatic sarcoma and carcinoma.
 2. Altered body metabolism—
 - a. Hyperparathyroidism,
 - b. Lipoid disturbances (Gaucher's, Christian Schuller, etc.)

To the surgeon and dentist this classification is more valuable than one developed on a strict pathological basis of truly cystic lesions. It is important for the dentist to realize that "cystic" lesions of the mandible can be other than dental in origin and that they may not be primary in the mandible, but metastatic. Consequently it behooves the dentist and dental surgeon to be fully cognizant of the variety of "cystic" lesions of the mandible and to make early provision for adequate treatment. By the same token the oral surgeon must be prepared at the time of operation to do either a relatively simple enucleation of a true cyst or a difficult radical resection of the mandible for a malignant tumor.

Roentgenographic and clinical characteristics of the ameloblastoma. The roentgenographic characteristics of the ameloblastoma are supposed to show multilocular radiolucent areas with a sharp smooth border. This is surrounded by a thin, narrow, radio-opaque zone. Smaller daughter areas connected with a larger radiolucent area have also been described as being characteristic. This description is probably better adapted to the cystic

phase of the tumor. There is no reason why any other cystic tumor should not look the same. Even solid tumors show a striking similarity. One should also remember that the ameloblastoma may be either unilocular, entirely solid, or solid and cystic and consequently the roentgenographic picture may be far from the "normal" (Fig. 1).

The ameloblastoma is generally considered to be a benign tumor. Because local recurrence is frequent, it has been sometimes said to be malignant. Complete removal of the tumor is made more difficult because of daughter cysts. Consequently what is believed by some to be a local recurrence is actually an incomplete removal. Rarely, the ameloblastoma will undergo true malignant degeneration and metastasize.

Because the ameloblastoma is generally considered to be a benign tumor, and because the roentgenographic pictures may be similar to malignant lesions primarily or secondarily in the jaw, it is of paramount importance to make an early correct diagnosis.

SUMMARY AND CONCLUSIONS

Multilocular radiolucent areas in the roentgenograms of the mandible have been demonstrated for ameloblastoma, multiple follicular cyst, giant cell tumor (local and general in origin), fibroma, fibrosarcoma, osteogenic sarcoma, and metastatic carcinoma (breast and thyroid).

The diagnosis of an ameloblastoma or of any other tumor of the mandible should not be made by means of the roentgenogram alone. There can be a wide variation in the roentgenographic findings of different ameloblastomas and they may simulate other tumors. And conversely other tumors of the mandible may simulate the ameloblastoma on the roentgenogram.

The primary value of the roentgenogram is to demonstrate the site and extent of the multilocular lesions of the mandible.

THE CHERNEY INCISION AS APPLIED TO THE SURGERY OF THE LOWER URETER AND BLADDER

DONALD R. SMITH, M.D., San Francisco, California

WHILE the suprapubic midline or low rectus incisions afford good exposure for most procedures directed toward the bladder and lower ureter, instances occasionally arise in which these approaches seem inadequate, particularly for surgery of the deep extra-peritoneal pelvic zone, the extensive dissection necessary for total cystectomy, or for surgery of the vesical neck or subsymphyseal urethra. A transverse low abdominal incision has been recently described by Cherney which allows of extensive exposure of the lower portion of the peritoneal cavity for surgery of the lower bowel and female reproductive organs. This incision, which is readily applicable to urologic procedures, is described in the following paragraphs.

From the Division of Surgery, Subdivision of Urology, University of California Medical School, San Francisco.

Read at the annual meeting of the California Medical Association in Los Angeles on May 7, 1945.

The transverse skin incision is curved slightly, with its convexity directed downward, and extends from just medial and inferior to either anterior superior spine of the ilium (Fig. 1). The wound thereby passes through the upper pubic hair line, often following a normal skin fold, and is carried down to the aponeurosis of the external oblique muscles and the sheaths of the rectus. At either extremity of the incision the superficial epigastric vessels are encountered and one or both may be sacrificed for added exposure.

The sheaths of the rectus are then opened transversely in line with the skin incision and the internal and external oblique aponeuroses are next incised to the angles of the wound. In this portion of the incision, the internal oblique muscle becomes fleshy but, since its fibers run in line with the wound, the muscle may be split further by blunt dissection. Occasionally the transversus muscle is present

Fig. 1 The incision through the skin, sheaths of the recti, and lateral abdominal muscles. P, designates pyramidalis muscles under linea alba

Fig. 2. The completed transverse incision. The pyramidalis muscles are separated from the underlying recti. The rectus muscles are transected through their points of origin on the pubis.

in the lower abdominal wall and then it also must be opened. This exposes the rectus muscles in the midline and the transversalis fascia and underlying peritoneum laterally.

Traction is next applied to the inferior flap of the sheath of the rectus and by gauze dissection it is freed from the underlying rectus muscles down to the symphysis pubis. A central fibrous septum extending from the under surface of the rectus sheaths to the recti must be cut and the pyramidalis muscles freed from the anterior surface of the rectus muscles (Fig. 2). The inferior ends of the recti then are separated from the underlying transversalis fascia and it will be noticed that

Fig. 3. Closure. The tendinous edges of the rectus muscles are resutured to the symphysis or under surface of the rectus sheath. The lateral abdominal muscles and the sheath are closed in one layer with interrupted sutures.

they become largely fibrous or even completely tendinous at their points of origin. The rectus muscles are cut off flush with the pubic bone, their tendinous ends being preserved for later resuture. The recti then retract well up to the upper border of the sheath of the rectus, exposing an elliptical space averaging 7 inches by 5 inches in its transverse and vertical axis respectively, an area twice that afforded by the midline incision and with its transverse axis much closer to the symphysis pubis than that of the latter. The transversalis fascia is then opened and the surgeon is prepared for wide exposure of the bladder or lower ureter.

Fig. 4. a, left, Exposure gained with Cherney incision allowing excellent access to the deep extravescical space.

Compare with the limited exposure afforded by the vertical midline incision, b.

Fig. 5 Repair of vesicovaginal fistula adjacent to left ureter. Fistula excised and both vaginal and vesical openings easily inverted

In the closing of the wound, the tendinous ends of the rectus muscles are first resutured to the under surface of the lower flap of the sheath of the rectus at or near the symphysis (Fig. 3). While considerable tension upon this suture line might be expected, it must be remembered that the rectus muscle is strongly attached on its anterior surface to the anterior sheath of the rectus by three or more transverse tendinous intersections so that when the transverse incision through the aponeuroses of the lateral abdominal muscles and rectus sheaths is sutured, the sheath itself takes the tension of the upper two-thirds of the muscle. Drains may be brought out through the incision or through a stah wound.

Certain advantages which this incision offers suggest its employment for selected surgical procedures: the transverse wound is longer than the vertical incisions so that exposure is increased. Vertical wounds give limited exposure because of the convergence of the sheaths of the rectus muscles at either angle of the wound even with strong lateral retraction. The Cherney incision gives excellent exposure at the plane of the symphysis overlying the deep pelvic zone (Fig. 4). The transverse wound is a strong wound. No muscle is denervated, the lateral abdominal muscles and the recti are divided at different levels, less retraction is needed, and lighter anesthesia therefore can be used. The direc-

Fig. 6. Excision of vesical diverticulum posterior to right ureter. The use of the Cherny incision greatly facilitated its removal.

tion of pull of the oblique muscles with strain is parallel to the direction of the incision in their aponeuroses and all sutures are taken through fascia which makes for good healing, thereby decreasing the incidence of hernia.

CASE REPORTS

The following cases are presented to demonstrate the exposure obtained through this approach:

A woman, aged 20 years, developed a vesico-vaginal fistula following instrumental delivery of a stillborn hydrocephalic baby. Examination 8 months later showed the fistulous opening to be just lateral to the badly lacerated cervix and cystoscopy demonstrated the opening in the bladder to be 1 centimeter medial to the left ureteral orifice. Be-

cause of the proximity of the fistula to the left ureter, an approach affording good visualization of the area was deemed advisable, so a Cherny incision was used. After its identification in the region of the pelvic brim, the ureter was followed down to the bladder (Fig. 5), the bladder was opened, the fistulous tract excised, and the openings in both the vagina and bladder were closed by interrupted inverting sutures. A cystostomy tube was left in place for 10 days, and 2 weeks after surgery was performed the patient was voiding without vaginal urinary leakage.

A man, aged 60 years, had previously undergone transurethral prostatic resection but troublesome symptoms from persistent pyuria continued because of vesical diverticula in the region of the right ureteral orifice. Diverticulectomy was decided upon and the transverse incision was used because of the excellent exposure of the trigonal area which it affords (Fig. 6).

Fig 7. Resection of anterior half of urethra, U, bladder neck, and adjacent bladder wall for congenital defect of sphincter. In the closing of this defect, the distal suture in the urethra was easily placed even though it was situated below the inferior border of the symphysis pubis.

A girl, aged 6 years, complained of enuresis since birth as well as incontinence during the day. Renal function and urinalysis were normal. Cystoscopy demonstrated a markedly relaxed urethrovaginal sphincter and a patulous urethra. The anal tone was intact. Neurological examination revealed no sensory or motor changes and intravenous urograms were normal. Roentgenograms of the bones of the lower spine and pelvis showed them to be normal except for separation of the symphyseal rami by a distance of 1 inch. This suggested the probability of an anterior defect of the vesical sphincter such as one might observe in a minor degree of exstrophy, so it was thought advisable to explore the neck of the bladder and the urethra. Exploration was done through a Cherney incision with admirable exposure resulting (Fig. 7). The anterior half of the urethra and vesical neck were resected and the remainder closed, the deepest suture being placed inferior to the lower border of the symphysis pubis under direct vision.

The results obtained for these patients might not have been as satisfactory if an

approach offering less exposure had been chosen. One of the fundamental rules of good surgical technique is to gain adequate exposure. The Cherney incision fills this requirement in a superior manner.

SUMMARY

1. The Cherney incision offers excellent exposure of the extravescical trigonal area (juxtavesical stone, diverticulum of the bladder, vesicovaginal fistula, etc.), vesical neck and subsymphyseal urethra. It is peculiarly suited for total cystectomy.
2. The technique of the approach is described.
3. Cases are presented which illustrate its advantages.

THE EXPOSURE OF HIGH LESIONS OF THE SCIATIC NERVE

IAN AIRD, Ch.M., F.R.C.S. (Ed.), Edinburgh, Scotland

THE inadequacy, difficulty, and danger of the classical nineteenth century approach to the structures under cover of the gluteus maximus through an incision in the line of its fibers were exposed by Fiolle and Delmas, whose 'trapdoor' elevation of the gluteus maximus can now be regarded as the standard procedure. A similar technique was described by Stookey, whose question-mark incision later authors have adopted. Henry has recently elaborated the operation, and has described its steps with a wealth of anatomical detail and argument which could hardly be more complete. In this paper a full description of the operation will not be attempted, but during the recent war certain problems in the management of high lesions of the sciatic nerve have emerged, and the measures devised to solve these may be added to the operative procedure.

The main difficulties encountered in the repair of a lesion of the sciatic nerve at its emergence from the pelvis are four in number: (1) hemorrhage from the branches or the main trunk of the inferior gluteal vein; (2) retraction of the neuroma into the pelvis; (3) inability of the nerve to rotate for the insertion of the anterior layer of sutures; and (4) liability of the posterior cutaneous nerve of the thigh to injury, not when the fascia of the thigh is incised initially, but when it is closed at the end of the operation. How these difficulties occur and how they can be overcome, are best illustrated by a brief description of the operation.

The incision (Fig. 1). With the patient prone and the knee pillowed to hyperextend the hip, the incision is begun at a point on the crest of the ilium a handsbreadth in front of its posterior superior spine, and the knife is drawn down to the tip of the greater trochanter, over the lateral aspect (not the posterior edge) of the trochanter, and then in a curve inward to the junction of the gluteal fold with the posterior axial line of the thigh. From this point the incision passes vertically downward toward or into the popliteal fossa as far as may be required for the adequate mobilization of the distal segment of the sciatic nerve.

Division of fascia. In the lower (vertical) part of the wound the fascia of the thigh is incised parallel to and just lateral to the posterior cutaneous nerve of the thigh, whose white outline is clearly visible through the fascial sheet. The lower edge of the gluteus maximus is defined between the point of emergence of the posterior cutaneous nerve of the thigh and the femoral insertion of the muscle.

Mobilization of the gluteus maximus. In the outer part of the wound, a vertical incision is made down to the lateral surface of the greater trochanter through the iliotibial tract. This provides the most convenient access to the space deep to the gluteus maximus; elsewhere a subgluteal plane of cleavage is difficult to identify. A finger in-

Fig. 1. Incision.

Fig. 2. Division of insertion of the gluteus maximus.

serted through the fascial incision can be readily passed upward under the junction of the upper fibers of the gluteus maximus with the iliotibial tract, to serve as a director for the knife (Fig. 2). This incision continues upward to the superolateral border of the gluteus maximus, and then along that border, dividing the iliotibial tract and freeing the superolateral border of the muscle completely. Now that the superficial portion of the gluteus maximus is mobilized, all that remains is to pass a finger upwards from the outer end of the lower border of the muscle, close to the femur, and to divide the muscle fibers of the deeper part close to their insertion into the femur.

Retraction of the gluteus maximus: division of the piriformis (Fig. 3). A broad-bladed retractor elevates the gluteus maximus upward and medially to expose the piriformis and the structures emerging from the cover of its lower border, but the initial elevation of the muscular trapdoor must be gentle, for as it is retracted, the branches of the inferior gluteal vessels passing to its deep

Fig. 3. Elevation of the gluteus maximus: division of tendon of piriformis. Note the spread eagle stretching of the branches of the inferior gluteal vessels, and the risk of tearing at the multiple bifurcations between them.

surface are pulled dangerously taut. This danger is implicit in the observation of Fiolle and Delmas (p. 45 of the English translation) that "the superficial branches of the gluteal vessels which supply the muscular mass become tense, like cords, between the sciatic notch and the under surface of the upraised muscle." The main trunks of the inferior gluteal vessels are relatively fixed by the lower border of the piriformis, and sometimes absolutely fixed by scar tissue at their emergence from the pelvis, and tributaries of the gluteal vein may be torn. Bleeding is particularly obstinate if one of the muscular tributaries is torn from the parent trunk, or if two converging tributaries are pulled apart to provide a longitudinal rent splitting the parent trunk; such bleeding may be almost uncontrollable if the torn proximal end of the vein is fixed in the sciatic notch by dense scar tissue. However, if the tendon of the piriformis is now cut across close to its insertion (Fig. 3),

Fig. 4. Piriformis retracted with the gluteus maximus. Tension on the inferior gluteal trunks is lessened, a greater length of these trunks is exposed. The companion vessels of the sciatic nerve, and a laterally passing branch of the inferior gluteal trunk, have not yet been divided; their division will still further lessen the tension on the muscular branches. Note the additional length of the proximal cut end of sciatic nerve exposed by division of the piriformis.

Fig. 5. Suture of the gluteus maximus. Note the needle picking up the fascia of thigh clear of and well medial to the line of the posterior cutaneous nerve.

vided before the trapdoor is fully raised, there is less risk of tearing at their V-junctions with the branches to the gluteus maximus.

cleared at its margins by blunt dissection, and elevated by a rake retractor in the same direction as the gluteus maximus, some additional mobility is afforded to the main trunks of the inferior gluteal vessels (Fig. 4), and the anastomosing branches which course upward over the surface of the piriformis to meet the descending branches of the superior gluteal vessels are retracted in the same direction as the superior muscular branches. Even if bleeding occurs now, a substantially greater length of the main gluteal vessels is available for ligature. An additional safeguard against hemorrhage is the formal ligation and division of the companion vessels of the sciatic nerve, and any laterally directed branches of the inferior gluteal vessels. The former and one of the latter are shown undivided in Figure 4; if they are di-

vided before the trapdoor is fully raised, there is less risk of tearing at their V-junctions with the branches to the gluteus maximus.

Figure 4 shows a further advantage of the division and elevation of the piriformis—wider access to the proximal cut end of the divided sciatic nerve. In 3 patients with sciatic nerve lesions treated in 1945, the nerve had been wounded at such a high level, and its proximal end had retracted so far into the sciatic notch, that only the distal extremity of the neuroma could be drawn from below the piriformis. Division and elevation of the piriformis in each of these cases afforded access to just these few extra millimeters of the sciatic trunk which were necessary for trimming and suture. In 1 case suture was performed at the level where the nerve was beginning to broaden in its parent plexus.

Technique of anastomosis. If the normal technique of nerve suture is followed at this level, and the superficial row of sutures is inserted first, it

In contrast to the "passive types" are the "active types" of prostheses, the parts of which are activated in varying degree by muscle movement. Their many types conform to two main groups:

a. Some utilize the extraneous muscle movement in relation to remaining joints to effect movement in the prosthesis. Most of these rely on a development and practice with the same or opposite shoulder movement. The standard cleft hook is well known of this type, and Carnes' arm is probably the best of the many designs on this principle. Many others have become scrap metal. All employ strings, pulleys, cords, or wires which require unnatural action or motion for a function which does not fully duplicate hand movement. In general, their cumbersome action tallies badly with their nuisance value to all and what to most implies a hopeless range of personal endeavor, training, and concentration to make them effective.

b. The other main group of active prostheses involves the principle and subject of cineplasty.

Cineplasty. Cineplasty implies utilization of the muscles actually within an amputation stump to impart some of their normal function to an appropriate prosthesis. It requires some type of surgical operation on the stump by which the unused and wasting source of muscle potential is utilized. Function is produced in a way which cannot be achieved by other methods, for direct control of the mechanism can be effected by the same muscle groups which would normally be producing that same action in a hand. Normal psychomotor patterns are involved. There is no latent period of inertia in activating or training extraneous muscle groups, and the patient has encouragement in the first use of a cineplastic prosthesis. We must remember, however, that cineplasty implies a mechanical prosthesis, still with a nuisance value, a necessity for maintenance, and an absence of tactile facility.

The principle of cineplasty was elaborated about 1896 as a theory, by the Italian physician, Vanghetti. He was thinking for the mutilees among Italians fighting in Abyssinia at that time. Vanghetti himself did only experimental work, mainly on birds. It was long

before he could convince one of his compatriots—one Ceci of Pisa—to do the first human cineplastic operation. Such procedures, however, had no effective trial until the mutilées of the 1914-1918 war had accumulated. Then Sauerbruch in Germany and the Italian school at Bologna (Ceci, Putti, Galliazzini) did large numbers of these operations in special clinics where there was apparently a very close liaison between surgeon and prosthetist. The few references in British literature are either by extraneous observers at these clinics or by the Continental men themselves. There were sporadic and isolated trials by individual surgeons, but the method received no general acceptance or favor. American writers have been more enthusiastic—Kessler, who studied in the Sauerbruch clinic, is apparently a practiced exponent and advocate of this principle.

A necessity for the highest order of teamwork explains the apparent discrepancy; why cineplasty has achieved a success and favor only in special clinics where large numbers are done, and not in sporadic trials among isolated cases. The basic organization in the special plastic surgery clinics throughout British and Imperial countries, thanks to the teaching and inspiration of Sir Harold Gillies, has offered unusual scope for such teamwork. In this Unit, attached to a large city base hospital, and where we have extended our prosthetic facilities beyond the usual, we have thought fit to evaluate for ourselves—by a limited first hand trial—something of the place of cineplasty for the upper limb amputee. In so doing, both concerning the plastic operation involved and the prosthesis used, we have endeavored to make improvements in what we could discern of their more obvious shortcomings. This work has so far been confined to forearm cineplasty and our present conclusions are epitomized in two chapters: (1) The plastic operation involved, (2) The prosthesis used.

THE PLASTIC OPERATION

There are many ways in which the muscle function of an amputation stump can and has been tapped. Sauerbruch's method has apparently best survived the sieve of time and trial. By it, a skin lined canal is made through

individual muscles or groups of muscles in a stump. Through these canals are inserted pegs, the movements of which are transmitted by appropriate mechanism of a prosthesis to produce movement of an artificial hand.

The permutations of procedure which could be applied to the making of a skin lined tube through muscle are many, but in view of the work of such a skin tube, we consider the following general principles should be satisfied in its making:

a. The tube must be a soundly healed and stable structure.

b. Any local operative procedures involved should create a minimum of scar formation which is likely to embarrass mobility of the tube.

c. The stump to which the prosthesis has to be fitted should be left devoid of anesthetic areas, areas of vulnerable scar, and wherever possible devoid of free skin grafts. Free skin grafts on an amputation stump are not always a satisfactory proposition. They are potentially unstable with petty trauma and they become adherent to deep structures in some degree. If a free graft has to be used, it should not overlie the area of muscle transfixion or the end of the stump.

With these factors in view, one of us (B.K.R.) has evolved an effective cineplastic operation which can be done simultaneously with an amputation or reamputation. The muscle tube is made of a skin and fat flap, its line of suture is off the line of pressure of the transfixion rod. It is a one stage operation in which free skin grafts are not used, and which is devoid of undue risks with flap vitality.

This operation can be done without modification only where there is sufficient length of limb for the use of the skin flaps from the region to be amputated. We would emphasize on this basis alone, the value always of the most conservative primary upper limb amputations which would render such a subsequent procedure possible and satisfactory. If remaining length of limb does not permit of the operation, a compromise in the method is required, and use of a supplementary free skin graft may be necessary. Chief of the modifications we have used will be indicated after the one stage operation is described.

Cineplastic reamputation. The stages of cineplastic reamputation are best followed in reference to Figure 1.

1. *Surface markings* (Fig. 1, a) XX' is the line of election for constructing a skin canal through the superficial plane of forearm muscles. It represents the junction of the middle and distal thirds of the middle third of the full length of forearm. It is drawn at right angles to a line from the medial epicondyle to the midvolar wrist in the case of the flexor group, or a line from the lateral epicondyle to mid-dorsal wrist in the case of the extensor group of muscles.

This line XX' respects two primary anatomical considerations as pointed out by all exponents of Sauerbruch's principle: (a) The strongest available potential of muscle power and excursion is at the region where contracting muscle belly gives place to passive tendon. In the forearm, this potential is approximately in the distal third of its middle third. (b) The superficial forearm muscle groups have a slightly oblique set on account of their essential origins from the humeral epicondyle regions. This fact must be remembered so that the tubes are made through the muscles, exactly at right angles to their direction of pull.

These facts are best verified and marked before operation with a co-operative patient.

The line XX' is only an approximate estimate and because of unpredictable variations in individual amputation stumps with varying degrees of muscle retraction, we consider it best to approach this line with a demilunar skin incision YY' which will allow some variation of XX' according to exact findings. It will also ensure that there is no potential scar to become adherent to the muscle over its line of canalization.

Identifying and canalizing the muscles (Fig. 1, b, c, d). After the skin flap YY' is raised the deep fascia is incised and the superficial plane of muscles is identified. The flexor muscles selected for canalization are the flexor digitorum sublimis (superficial portion) and the flexor carpi radialis, both of which can be transfixied in the same plane. The main mass of the flexor carpi ulnaris is usually too far posteriorly to be included.

It is important to ensure that the tube actually passes through muscle substance—it is easy to slip in between muscle planes. In the first instance, transfixion is conveniently effected under careful vision, a pair of eye scissors being used (Fig. 1, c). This line of muscle transfixion is then dilated by successive passage of a special set of graded and interlocking solid metal dilators (Fig. 1, d). On the two larger of these can be fitted and passed through the muscles bored hollow metal tubes which measure $\frac{1}{2}$ inch by $\frac{5}{8}$ inch. The smaller tube is used for small limbs or if further dilation proves difficult. The appropriate hollow tube is left *in situ* as a dilator while the skin tube is being made.

3. *Designing and making the skin tubes.* On the ulnar side of the forearm, a rectangular skin flap *ABCD* is designed (Fig. 1, e) with its base *AB* obliquely across the transfixion line *XX'*, its sides parallel, and its dimensions depending on the length and bore of the muscle canal. In an average case, this requires a flap approximately $2\frac{3}{4}$ inch by $1\frac{1}{2}$ inch.

After the flap is carefully raised on the base *AB* (Fig. 1, f), it is turned in to make a skin lined tube. This step is facilitated by first inserting at each end an inverted end on mattress stitch, tied with knots on the skin surface. These are used as stay stitches. One stitch coapts *C* and *D*, but the other must be sufficiently distant from *A* and *B* to allow the skin edges to come together without undue tension (Fig. 1, g). After an appropriate size rubber tube is inserted, the skin lined tube is completed by a continuous subcutaneous running stitch which is first tied to the near stay stitch and finally to the far stay stitch (Fig. 1, h). An assistant holds appropriate tension in the continuous stitch during its insertion. Fine silk on an atraumatic needle is used.

4. *Passing the skin tube through the muscle canal.* With the aid of a pair of sinus forceps passed down the metal tube from the end opposite the base of the skin tube, the stay stitch and rubber tube at its free end are guided into the near end of the metal tube which should not be projecting far beyond the muscle opening on that side (Fig. 1, j, h). The skin tube is then drawn carefully into the metal tube. On removal of the metal tube

from the far side, the skin tube is left *in situ* through the muscles (Fig. 1, i). This method radically simplifies what is otherwise a very tedious procedure.

5. *Completing the skin tube.* The initial exploratory flap is then resutured in place and the open ends of the skin tube are carefully sutured all around their margins to outside skin.

On the dorsum of the forearm, the same procedure is repeated in complementary design. The extensor digitorum communis and extensor carpi ulnaris muscles are used, but the canal is usually slightly shorter than that through the flexor muscles. In this case, the flap used for making the skin tube is designed on the radial side of the forearm.

When both tubes are completed, there remain two secondary defects which are the donor sites of the skin tubes—one on the ulnar side of the volar aspect, the other on the radial side of the dorsal aspect of the forearm.

The Reamputation

Two amputation flaps are raised on lateral bases, but contain skin from the volar and dorsal surfaces of the forearm respectively (Fig. 1, j, k, l).

The anterior flap *EFGH* is raised on an oblique base *EF* on the radial side of the limb. It consists essentially of volar skin. The posterior flap *JKLM* is conversely raised on an oblique base *JK* on the ulnar side of the limb and it consists essentially of dorsal skin.

It will be noted that each of these flaps consists mainly of the skin distal to the raw areas. When rotated in opposite directions they close these areas as well as the site of reamputation.

These flaps must be designed very accurately and carefully. The skin areas proximal to their base lines *EF* on the radial side and *JK* on the ulnar side as represented by the shaded areas on Figure 1, j, k, l, might well be described as "the critical areas." There must be no undermining of skin edges in this region, on which depends the existence of the flaps. This step constitutes one of the main points of the operation. The free distal end of the one flap is on the margin of the critical area of the other flap.

After the flaps are raised, the muscles are divided at a level as far proximal as the bases of the flaps will allow, care being used not to jeopardize their blood supply further (Fig. 1, l). After proximal traction on the severed muscles, the bones are divided at a level slightly proximal again to the severed muscles.

After routine hemostasis is effected, the deep muscles are sutured over the dorsal ends, but the superficial groups which have been canalized are left free to retract.

Final Suturing

Rotation of the volar and dorsal flaps in opposite directions (Fig. 1, m) allows each to close the donor site of the skin tube on its respective aspect without undue tension, and the distal curved margins of each flap are sutured one to the other over the amputation site. This method makes a curved suture line in a coronal plane around the end of the stump.

Silk sutures are used throughout with every precaution and finesse for accurate edge-to-edge apposition.

The final arrangement and suturing is shown in Figure 1, n, o, p.

Rubber tubes are left through the skin tubes, but they must not be too large and tight.

A routine dressing and light crepe bandage pressure is arranged over the whole stump. This is left undisturbed for a week.

Postoperative Management

At the first dressing, 1 week after operation, half the superficial stitches are removed. The rubber tubes are removed from the skin tubes. The continuous stitch through the length of the skin tube is carefully identified from its fixation to the two separate end stitches, and all are carefully removed. If the running stitch feels tight, it is left a few days longer.

Through the skin tubes are then passed acrylic rods made to appropriate diameter. It is important to see that for a time these are always passed from the base side of the skin tube flaps and removed from the opposite side.

Remaining sutures are removed a few days later, after which the rods are removed daily for routine toilet of the skin tubes.

Healing should be complete in from 2 to 3 weeks, when voluntary active contractions of the appropriate muscles are commenced. Function is slowly increased, and after another 2 weeks, exercising against increasing resistance is arranged as in Figure 2. Exercise is continued until adequate force and excursion are developed when the appropriate prosthesis is fitted. Average excursion is $\frac{1}{2}$ inch to $\frac{3}{4}$ inch for the flexor rod and $\frac{3}{8}$ inch to $\frac{1}{2}$ inch for the extensor rod. The final result and appearance is shown in Figure 3.

Variations from the Described Operation

It is obvious that the one stage cineplastic reamputation implies an adequate length of amputation stump, i.e. more than $\frac{2}{3}$ of the forearm must be present, otherwise there is insufficient local skin flap available for the operation described without undue tension.

For stumps already too short for the cineplastic reamputation as described the following may be necessary:

1. In most of these cases it is usually necessary to use a free skin graft on the donor site of the skin tubes. As a free graft on an amputation stump is always a vulnerable area, if one has to be used it should not be placed over the end of the stump, nor do we consider it should be over the muscle tubes where its contraction and associated scar would embarrass the desired function of the tube. This point we consider the main disadvantage of the simple and commonly used method of making a skin tube through muscle as practiced by Sauerbruch and advocated by Nissen and Bergmann in their excellent monograph on this subject. If a free graft is required, the skin tube can be made exactly as described in the elective operation, and the secondary defects grafted as they stand with thick split skin (Fig. 4). In one case, contraction of the graft did produce a bad distortion of an extensor tube which had to be abandoned.

2. *The single tube operation.* In some cases, rearrangements of the amputation flaps will permit of making one skin tube without resort to free grafts. In 2 cases, a well functioning flexor tube has been made and the prosthesis modified accordingly so that a light spring takes over the function of the extensor mus-

Fig. 1. a to h, Stages and technique of cineplastic reamputation of forearm.

cles. The possible advantages of this more simple procedure are still open to consideration and will be considered later.

3. *Use of abdominal flaps.* Some stumps still shorter, though still adequate for cineplasty, may not permit of free local use of skin for making skin tubes. Local scarring might also produce this same consideration. It may then be necessary to design and evolve skin tubes from other body regions in a staged operation (Fig. 5).

Disadvantages associated with any of these variations reiterate the advantages of the one stage cineplastic reamputation as described and again call for every effort to conserve

always the maximum length of upper limb in primary surgery of injury.

THE PROSTHESIS

In an endeavor to reduce some of the usual deficiencies pertinent to normal upper limb prostheses and other cineplastic mechanisms, we have concentrated in three main directions:

a. *The outward esthetic appearance.* It is considered that with the modern materials available, some better replica of the normal hand should be possible which would ensure its continued use on this score alone.

b. *An efficient, intrinsic mechanical leverage system*—to transmit the muscle power to move-

Fig. 1, i to p.

ment of artificial fingers in the most effective way.

c. Reduction of the total weight of the prosthesis—to well below ordinary standards.

To such ends, in 2 years of experimental construction and trial, in relation to a small series of selected cases, taking advantage of modern materials available and with many variations in their use and construction, we have elaborated a satisfactory working principle and prototype.

This forearm cineplastic prosthesis, which we call the Heidelberg pattern, is depicted in Figure 6. Its general mechanical arrangement and assembly is shown in Figure 7. Full de-

tails of all its essential parts are beyond the scope of this report, but its essential features will be expanded "seriatim" relative to (a) the hand superstructure; (b) the intrinsic mechanism; (c) the accessory fittings.

The Hand Superstructure

The hand superstructure is made in acrylic (methyl methacrylate) resin, as a hollow casing which minimizes weight and provides space for the mechanism. Acrylic was selected for its lightness and a transparency which renders it suitable for realistic color effects beyond that of ordinary materials previously used. In order to produce the exact replica of

Fig. 6. The "Heidelberg" prosthesis as it appears fitted to an amputation stump.

a normal hand, full impressions were first made from selected normal hands with a hydrocolloid impression material.¹ From these impressions, models of the hand were made in artificial stone.

The acrylic hand casing is made in 10 separate segments. Each of these segments is made in a die of plaster prepared from appropriate pieces of the stone model which is fragmented as shown in Figure 8. Use of a special tubular saw, illustrated in the same figure, permits of cylinders being taken out of the bases of both the thumb piece and the two adjoined opposing fingers. These regions constitute the only two ultimate moving joints of the prosthesis. The ring and little fingers are dummy.

Impression technique. Two ounces agar agar, 3 pints of water, small piece of soap (the size of a marble), a handful of cellulose wool. Boil the water and pour over the Agar (cut agar into small pieces). Boil mixture in double saucepan until dissolved. Add soap and cellulose wool, stir well. Remove mixture from flame, allow to cool to blood heat, and apply with a soft brush. When well dry, cover with plaster of Paris. When plaster is dry, remove cast and pour up

Fig 9. To show the separate acrylic segments of the hand casing and something of their assembly: A, Segments of the finger pieces (6). B, Arrangement of assembled fingers and fitting of drums in the cut-out bases of thumb and the two fixed opposing fingers. The dural bases of the acrylic coated drums are shown. C, Front and back portions of the hand proper—2 sets, showing the fitting of the finger drum and early stages of infitting the mechanism. D, Separate halves of the wrist casing

color can be added to the external surface by painting with an acetone solution of appropriate pigment.

A disadvantage of acrylic is its smooth, hard, slippery surface, unsuited to the handling of small objects. To offset this, the contiguous surfaces of thumb and opposing fingers are cut out with a drill and the defect made up by in-fitting cushions of polyvinyl chloride (artificial rubber). These pads are made concave on their inside, which increases the cushion effect. They are processed in place with acrylic gum.

The separate pieces of the hand casing are fused together by a thin mix of acrylic or a special gum. Volar and dorsal halves are left separate until the mechanism is in-built. The in-building is facilitated by provision in the internal structure of the shell of appropriate

platforms and projections for attaching the mechanism.

The Intrinsic Mechanism

Details of the intrinsic mechanism are represented in the "exploded" diagram, Figure 10. Mild steel case hardened, duralum in and brass are all used in the mechanism, with a view always to the most effective combination of lasting strength and lightness.

The essential principle consists of a transmission of the muscle pull by a system of stirrups and transmission rods to a double toggle system of levers. One of these toggles effects movement of the thumb by its attachment to a drum in the thumb joint. The other toggle similarly effects movement of the fused index and middle fingers. Intercepting the

Fig. 10. Mechanical layout of cineplastic hand prosthesis, Heidelberg pattern. (Details concerning mechanism to be obtained by writing authors.)

transmission rods is a brake drum which serves a three-fold purpose: (1) it projects extensor and flexor muscle function, acting in converse ways to the common toggle system; (2) it has an equalizing effect on the difference in power between flexor and extensor muscles; (3) it acts as a locking device, so that a fixed grip can be maintained in any position without continued muscle effort.

The chief features effecting this mechanical principle are:

1. *Metal stirrups.* Each stirrup forms a spring clip with the metal core of acrylic rods which are made to fit the muscle tunnels in the stump.

2. *Connecting rods.* These are attached to the center of each stirrup and include hinges to give a universal movement. The flexor rod is attached to the lower portion of the brake drum, but its effective pull is continued by the toggle system. The extensor rod is attached to the opposite diameter of the brake drum surface.

It will be noted that by this arrangement, both flexor and extensor rods can produce

their contrary effects on the common toggle system.

3. *The brake drum and locking device.* This feature essentially consists of a drum turned to shape from dural rod (Figs. 11 and 7). Into the drum are fitted friction or brake shoes which are brought into the locking position by a cam shaft operated by a lever, which passes

Fig. 11. The brake drum and locking device, and its location in the wrist casing.

Fig. 12. The general appearance and usefulness of the Heidelberg pattern forearm cineplastic prosthesis.

through the wrist casing. The shoes are brought firmly against the inside of the drum to act like the brakes of a car.

The operating lever is fitted with a tension spring arranged in an eccentric manner to hold the lever in either the locked or unlocked position.

On the smooth surface of the drum the connecting rod from the flexor stirrup to the toggle system is intercepted by and runs freely on a screw which is placed as near as possible to the edge of the drum. With muscle contraction to close the finger, the drum revolves with the pull of the flexor rod. Diametrically opposite on the drum, the extensor operating rod is attached by a screw to a slotted plate on the drum. This plate can be moved in or out from a central position, so altering the radius and increasing or decreasing the length of effective pull of the extensor rod. By this

means, variation in the relative strength of the extensor muscle is catered for. The relatively weaker pull of the extensor muscles is also assisted by an antagonizing spring on the flexor connecting rod.

4. *The finger drums.* The finger drums form the mobile joints of thumb and apposing fingers. Each consists of a hollow duralumin drum with fitted ends and coated with acrylic (Fig. 9). Through the center of each drum, a core of duralumin tube serves two purposes. To it is fixed the metal lever on which the toggles are attached, and it also accommodates bearings at either end in which fit stainless steel pins forming the axle of the drum.

The Accessory Fittings

The wrist portion of the assembled hand is attached by duralumin bars (1) to a leather

and/or metal cup¹ which must be made for each case to fit accurately to the end of the amputation stump. It acts as a counter pressure point for the effective pull of the muscles through the intrinsic mechanism. (2) The bars further extend to a second attachment on one ring of a ball race situated at a level below the elbow region.

By the ball race, some pronation and supination movements are obtained. The other ring of the ball race is attached by elbow hinges to a well fitting but not tight molded armcuff. The cuff is trimmed and arranged so as not to embarrass the biceps muscle. The usual accessory body straps are attached as required.

THE MODIFIED HEIDELBERG PROSTHESIS FOR A SINGLE TUBE CINEPLASTY

In these cases, only the flexor muscles are used. All parts of the prosthesis pertinent to the extensor muscles are dispensed with. The opening of the grip is effected by a spring, antagonizing the flexor rod in a position as indicated in Fig. 7.

Considered advantages of the Heidelberg prosthesis are:

1. *A high standard of esthetic appearance.* All of the amputees so far supplied with these arms continue to wear them, and, when carefully questioned, one of the chief reasons is that they "look well" (Fig. 12). To personnel in a sedentary type business occupation, as most of our small series are, this is a good reason. Acrylic is not the ideal medium, but it does set a high standard in this regard for future materials and improvements.

2. *The mechanical lever system* is simple and efficient, and effects a good useful range of strong finger movement.

3. *The locking device* permits of the prostheses being used in a passive manner. Long continuous gripping of objects—e.g. pen or knife—can be effected without continued muscle action. Metal clips on the common utensils are required to stabilize the grip by the nonresilient acrylic (Fig. 12).

4. *Total weight* of recently completed prostheses with all accessory fittings is 1 pound

8 ounces. This is much lighter than the dress arm normally supplied.

5. *The hand is durable and serviceable* despite a highly esthetic and somewhat fragile appearance. These hands have given little trouble in our small series to personnel outside the manual laborer class.

The chief disadvantage of the prosthesis is the limited effective range of the finger movement (only $1\frac{3}{8}$ inch). This is dictated by the space available for the lever system. We consider this may be improved by modifying the lever system and using a "knuckle joint" or a "sliding plane" in the thumb system, if not in the opposing finger system as well.

RESULTS

Our experience of cineplastic amputations is confined to the forearm and that limited to 12 cases. It is recognized that only by a large case series carefully controlled over a long period could any finite conclusion be made, but in view of the times and our early encouragement, we consider such an interim statement indicated, immature though it is. All patients fitted with a cineplastic prosthesis continue to wear them to date, and remain enthusiastic. That must be the ultimate judgment of their value. Kessler in America states that 60 per cent of the 264 cases continue routine use of their prostheses. Jottkowitz quotes 40 per cent of his 728 cases, while in the Saurbruch clinic, 60 per cent of 304 cases are recorded as satisfied.

Careful preselection of cases must be made the prime factor for the success of any cineplastic procedure. No procedure would be more doomed to failure by any haphazard or mass application. All types of upper arm prostheses have their limitations—a cineplastic is one of them. Some individuals may be of such mental caliber or vocation that they would be better without any prosthesis at all. Some may be better suited to a bucket with attachments; others may require only a cosmetic substitute, or may need and derive great benefit and help from a cineplastic prosthesis.

A cineplastic prosthesis is not something automatic, but something of, which the wearer must learn the true use himself. Cine-

¹In recent models, these cups have been made of reinforced acrylic, as shown in Figure 6. Polyvinyl chloride may be a still better medium for this purpose.

plasty is no proposition for a flabby personality. In the preselection of cases, the chief considerations are:

The individual, his attitude, and will. He must be fully informed of the implications of the procedure, and its limitations. The early expectations of upper limb amputees are often too great. The salesmanship of a manufacturer or town gossip may contribute to this mistake, which should never be allowed to continue for any lack of careful explanation. Sad realization of the gross inadequacy of an artificial arm when supplied as compared with that of his hopes, has—in the past—often led not only to its rejection, but to a deep-rooted prejudice for any appliance. An amputee can always escape in an unfortunate sense of honor to have lost an arm and to show it.

Type of work or vocation. Forearm cineplasty is most satisfactory for a sedentary type occupation. It is of little use to the manual laborer for his work, but even he may value it in sedentary life and leisure. It is not incompatible with the alternate use of other limbs and appliances on the same stump.

The amputation stump. Prerequisites in this regard have been set out. There must be adequate length of forearm to permit a satisfactory cineplastic operation. We have had no experience with upper arm cineplasty, but the prosthetic technical difficulties associated with it must range against its relative value.

Site of amputation relative to dexterity. All right-handed amputees or their left-handed counterparts who are missing on the same side, would be better considered for a cineplasty than those missing on the opposite side. The bilateral amputee would seem always the strongest indication for cineplasty.

CONCLUSION

We believe with modern progress both in plastic operations and a better order of prosthesis, that cineplastic procedures as described must have a wider application than we know of at present.

It is hoped that our experiments and results might stimulate trial on a larger scale than our numbers, time and facilities might permit.

There are many ex-service personnel who have lost their right hands in the service of their country and their fellows, and their least dessert is the pan-ultimate that modern science and surgery can contribute to their re-construction.

THE EFFECT OF PULMONARY RESUSCITATIVE PROCEDURES UPON THE CIRCULATION AS DEMONSTRATED BY THE USE OF RADIOACTIVE SODIUM

SAMUEL A. THOMPSON, M.D., F.A.C.S., EDITH H. QUIMBY, Sc.D.,
and BEVERLY C. SMITH, M.D., F.A.C.S., New York, New York

IN asphyxia, the object of all resuscitative procedures is to produce an adequate pulmonary ventilation. Negovski and his co-workers have recently added to pulmonary ventilation, the intravascular injection of oxygenated blood and glucose in their efforts at "revival" (1). The majority of investigations in resuscitation have dealt with the degree and efficiency of the ventilation produced by the various methods. Such ventilation occurs as a result of: (a) inflation of the lungs and return to the starting point; (b) deflation of the lungs and return to the starting point; (c) alternate inflation and deflation of the lungs. The procedures are classified as manual or mechanical, and are of various degrees of efficiency. A measured and constant amount of ventilation can be produced only by mechanical means, controlled by either a constant volume or a constant pressure. Large volumes or excessive pressures may cause alveolar rupture and for this reason controlled pressures are safer than controlled volumes. Only resuscitators with a controlled pressure should be used. No control or constancy exists with any manual method.

Pulmonary ventilation alone is insufficient to produce resuscitation, particularly when circulation has stopped. Oxygenated blood in the lungs is of no value unless it can be moved out and transported to the vital centers of the nervous system. Such a movement of the blood does take place in certain methods of resuscitation, varying in rate and volume with the method used.

Very little emphasis has been placed upon this aspect of resuscitative procedures, and no definite study appears to have been made of it. Actually, until recently there has been no satisfactory way of demonstrating whether or not any given procedure could produce an actual movement of the blood column. The purpose of the present paper is to describe a method for determining the relative effects of various types of pulmonary resuscitation upon the circulation, and to give some experimental results obtained thereby.

This method consists essentially in introducing a tracer substance into the vascular system of an animal immediately following death by asphyxiation and recording any movement of this substance during the application of the resuscitative procedure. The tracers which have been employed are radioactive sodium, fluorescence, and oxygen. This concerns the use of radioactive sodium only.

The use of artificially radioactive isotopes as tracers has become rather familiar in the field of experimental medicine in recent years. Sodium, used in the present study, is made radioactive by deutron bombardment in the cyclotron and then emits penetrating radiations which can be detected by means of a Geiger-Mueller counter. A small amount of this material, in normal saline, injected into the circulatory system of the living animal, is rapidly carried throughout the body; its presence in any region can be demonstrated by placing the counter against the surface of the body at that part (2). In an animal whose circulation has ceased, such distribution could not occur. A counter placed over the body at a place distant from the site of injection would register only a small background count, due

to the presence of the sodium in the distant region. As long as the radioactive material remained essentially at this position, the count would remain the same. If, however, any movement of the blood in the veins and arteries could be brought about by a resuscitative procedure, the radioactive sodium would also be moved, and any appreciable shift toward the counter would be demonstrated by an increase in the counting rate.

TECHNIQUE

Dogs 14 to 20 kilograms in weight were used, the following procedure being carried out: The animal was anesthetized with intravenous or intraperitoneal nembutal. An endotracheal tube with occlusion cuff was then inserted and the cuff inflated to make the tube leak-proof. To prevent intravascular clotting of the blood, 2 to 5 cubic centimeters of

heparin were injected intravenously. Approximately 5 minutes after the injection of heparin the endotracheal tube was completely clamped off, and the animal allowed to succumb to obstructive asphyxia. Cardiac cessation and death according to clinical evidence took place about 8 to 10 minutes after the tube was clamped. However, in order to insure complete death with no subsequent cardiac activity, the tube remained clamped for an additional 20 to 30 minutes. The animal was placed on an inclined plane, with the head elevated about 20 degrees, to counteract any possible effect of gravity in causing diffusion of the tracer substance toward the heart.

At the end of this time about 2 cubic centimeters of normal saline, containing 50 to 60 microcuries of radioactive sodium were injected into a femoral vein or artery. The Geiger-Mueller counter was placed against the neck of the dog, in proximity to the carotid artery, and the resuscitative procedure started and carried on for 40 to 60 minutes.¹ During this period, starting at the instant of injection of the radiosodium, the counts per minute registered by the counter against the neck were recorded. These counts were plotted on a curve showing any change in counting rate with time after the start of resuscitation (Chart 1).

After the mechanical procedure had been carried on for this period, and the effect was evident, the resuscitator and counting were stopped and 5 cubic centimeter blood samples taken from the femoral vein and artery on the opposite side from that injected, the right and left side of the heart, the jugular vein, and one carotid artery. Careful measurements were made of the amount of radioactive sodium contained per cubic centimeter of each of these samples (Tables I and II).

Experiments were carried out with various possible combinations of conditions:

Intravenous sodium with (a) alternate inflation and deflation of the lungs; (b) inflation and release; (c) deflation and release.

Intra-arterial sodium with (a) alternate inflation and deflation.

¹The resuscitators used positive pressure of plus 14 millimeters of mercury, negative pressure of minus 9 millimeters of mercury. The rate was set at 16 to 20 per minute.

TABLE I.—RADIOIODINE CONTENT OF DOGS' BLOODS

No. of experiment	Weight of dog kgm	Type of resuscitative procedure and site of injection	Assumed blood volume c. c. (1/7 weight)	Microcuries radioiodine injected	Microcuries per c. c. if entire dose were uniformly distributed*
1	10.5	Intravenous sodium I ¹³¹ heparin Double action respirator	2700	50	0.018
2	18.7	Intravenous sodium I ¹³¹ heparin Double action respirator	2670	50	0.019
3	16.7	Intra-arterial sodium I ¹³¹ heparin Double action respirator	2300	50	0.022
4	20.8	Intravenous sodium I ¹³¹ No heparin Double action respirator	2070	60	0.020
5	16.5	Intravenous sodium I ¹³¹ heparin Suction only	2360	60	0.025
6	16.9	Intravenous sodium I ¹³¹ heparin Pressure only	2410	40	0.021
7	11.8	Intravenous sodium I ¹³¹ heparin No respirator	1970	50	0.025

*Actually some of the sodium would have passed into the extravascular fluid, so this value is probably somewhat high.

Controls, with intravenous sodium with (a) heparin with no resuscitative procedure; (b) alternate inflation and deflation with no heparin.

RESULTS AND DISCUSSION

A heparinized animal recently succumbed to obstructive asphyxia provides an ideal subject for observing the effect of any given resuscitative procedure upon the circulation, provided a tracer can be introduced into the blood so that its movement can be followed. Any such movement would depend on the fact that the mechanical inflation and deflation of the lungs produce a regular filling and

emptying of the pulmonary capillaries and a regular alternation in pressure upon the heart and great vessels of the mediastinum. Since the valves of the heart and veins prevent a back flow of blood, any movement of the circulation must be in one direction, and if of sufficient rate and volume would complete the circuit from left heart to artery, to capillary, to vein to right heart, to lungs, and thence back to left heart again. Such movement of blood containing radioactive sodium could be detected by the Geiger-Mueller counter, its rate recorded, and some idea obtained of its volume.

*No samples could be taken from this dog having no heparin

The experimental data for 7 dogs are shown in Chart 1. Animal 7, the control with no resuscitative procedure but with heparin and radioactive sodium, showed no increase in count at the neck during 40 minutes. This demonstrates that there is no significant motion of the sodium due to diffusion or any other process occurring when no resuscitator is employed. In animal 4, the control having no heparin, the count rose only very slightly. On postmortem examination a large clot was found in the abdominal inferior vena cava, which would have prevented any further passage of radioactive sodium beyond this point. With all of the other animals, after a short period the count began to increase, and continued to rise as long as it was followed, up to an hour. In all except animal 2, there was a delay of 15 to 20 minutes before definite change was evident; this one animal showed an immediate rise and went much higher than any other. The reason for this is not evident; there seemed to be no doubt that the dog was dead, although an extremely weak heart action would account for the finding.

With the exception of animals 1 and 2, each one was subjected to a different procedure from all the others, so that there is no data as to possible variations among animals treated in any one particular manner. Hence it is not possible to put much stress on the numerical differences in the results. However, the two dogs in which alternate inflation and deflation were employed (animals 1 and 2) and the one having deflation and release (animal 5) showed values definitely higher than the others. The one having inflation and release (animal 6) came up more slowly, as did the one in which the injection was intra-arterial (animal 3). This latter was to be expected, since the material would have to be moved first through the capillaries and then into the veins before it could start toward the heart.

The radiosodium contents of the blood specimens from the various dogs are given in Table I, with other pertinent data. It is assumed that the blood is 7 per cent of the body weight, and microcuries per cubic centimeter are calculated for uniform distribution throughout the circulatory system. This

amount is what would be expected in a living dog, when mixing through the blood was completed, before diffusion into the extravascular fluid had proceeded to any significant degree. In none of the asphyxiated dogs was this distribution approached.

Certain suggestions may be advanced to explain the results in the various animals, but it must be recognized that these are tentative and could be confirmed only by repeating each test on several dogs of essentially the same weight. For instance, in animal 3, having intra-arterial sodium, apparently the procedure was not carried on long enough for the material to travel through the capillaries of the injected leg to the veins, to the heart, to the artery of the opposite leg, and through the capillary system of the opposite leg to the vein, for no active material was found at that site. Similarly it was low in the jugular vein. However, the variations in values in all the examinations indicate that the mixing of the radiosodium in the blood is far from uniform, as would be expected with this type of forced circulation. The actual radiosodium contents of the blood samples may not have much significance. The important thing is that grossly, with the counter, general movement in the circulation can be observed.

From these experiments it is quite evident that in a dead animal the mechanical inflation or deflation of the lungs or a combination of both produces a movement of the blood of sufficient magnitude to circulate it over the entire body, in a continuous direction from vein to heart, to lungs, to heart, to artery, to capillary, and back to vein again. While both the rate and the volume of this circulation are well below that in the living animal, it is, nevertheless, definite. Whether it is a result of the alternate filling and emptying of the pulmonary capillaries or of alternation in pressure upon the heart and great vessels, or a combination of both, is not yet determined (3).

That it is possible by mechanical means to circulate the blood in an animal whose heart has stopped beating would seem to have considerable clinical value. In order for the blood to be circulated it must remain fluid. Intravascular clotting takes place soon after death, and when this occurs the possibility of recov-

ery is terminated. Therefore the use of heparin intravenously as an active part of resuscitation is indicated. If, in resuscitation, heparin is given intravenously before the heart has stopped beating, thus preventing clotting, the time of possible revival is prolonged. Since the greatest amount of circulatory movement was found with alternating positive inflation and negative deflation of the lungs, this should be the method of choice. This can be done only by mechanical means; it is therefore evident that mechanical double action respirators are of the greatest value.

Because of the small number of experiments, no definite numerical conclusions can be drawn from these results. However, movement of the blood in a dead heparinized animal has definitely been shown to occur under the action of mechanical respirators. The results have been qualitatively corroborated by other experiments (to be reported later) in which fluorescence and oxygen have been used as tracer substances. Quantitative results are more readily obtained by use of a radioactive tracer.

SUMMARY AND CONCLUSIONS

A method of determining the effect of pulmonary resuscitative procedures on the circu-

lation by the use of radioactive sodium has been described. By this method it has been possible to demonstrate that alternate mechanical inflation and deflation of the lungs, or either operation alone, produce a movement of the blood within the vascular system. This movement is sufficient in the dead but heparinized animal to circulate some of the blood throughout the entire body. Mechanical resuscitators, using alternating positive and negative pressures, produce the greatest circulation. As soon as postmortem clotting occurs, little or no motion of the blood can be brought about by resuscitative procedures. When intravenous heparin is used to prevent this clotting, the period during which blood can be moved is greatly prolonged. For this reason the use of intravenous heparin seems indicated in resuscitation, as a definite means of prolonging the possible recovery time of the asphyxiated patient.

CANCELLOUS BONE GRAFTS FOR INFECTED BONE DEFECTS

A Single Stage Procedure

Wing Commander HERBERT M. COLEMAN, M.D., F.R.C.S. (Ed.), Major JAMES E. BATEMAN, M.D., GORDON M. DALE, M.D., and Captain DONALD E. STARR, M.D.

THE skillful surgery of World War II, with the help of plasma, penicillin, and sulfa therapy has saved many lives and limbs which would otherwise have been lost. The reconstructive surgeon is subsequently faced with many difficult problems in the restoration of a limb. Large bone defects with scarring of the overlying tissues are frequently encountered after compound fractures or gunshot wounds. In cases in which the wound has never been infected or has been healed for several months, the problem is relatively simple and can be handled by one of the common methods of bone grafting. In those cases in which the bone defect has an associated chronic low-grade infection with sequestra and sinus formation, function must be restored quickly before infection and immobilization give rise to such disuse changes as stiff joints, atrophy, and fibrosis of muscles, together with circulatory changes.

In January, 1944, Dickson stated that, "a surgical bone graft should not be attempted in the presence of active infection even if low grade. An occasional success does not justify the risk of almost certain failure to be anticipated." "Placing a bone graft in an infected area, therefore, must be characterized as surgically unsound and a violation of the principles of bone graft surgery." In the series under review over the past 14 months, 52 infected bone defects have been cleaned out, filled with cancellous chip grafts and the wounds closed without drainage. This procedure, in direct violation of the principles here enumerated, has yielded results which are extremely gratifying. In only 4 cases has the result been unsuccessful with continued infection, resulting in sequestration

of the grafts or further sequestrum formation in the grafted bone. The remaining 48, or 92 per cent, are healed with the bone defects obliterated.

In the summer of 1944 several patients were admitted with sinuses leading down to large cavities in the upper end of the tibia (Figs. 1, a, b, c; 3, a, b, c; 12, a, b, c, d.). The defects were such that they could not be dealt with in the usual manner by saucerization or filling with muscle grafts. This type of osteomyelitis had been a problem after the last war, and many of them eventually came to amputation (Fig. 2). Visits to other orthopedic centers found these patients being treated from month to month with courses of penicillin or sulfa drugs without effect.

In view of good results following sequestrectomy with closure of wounds under penicillin and the successful use of chip grafts in the mandible by the plastic surgeons in the presence of infection, it was our opinion that cancellous grafts could be used in other bones as well. Mowlem (6, 7) has reported 85 cancellous chip grafts. Eleven of these were done in the presence of infection, 2 in the tibia and the rest in the mandible and skull. He considers fragmentation of the graft provides a greater surface through which transplanted bone cells become accessible, first to serum and then to newly formed capillaries, thus making their survival more certain. We have confirmed his observation that cancellous bone has an unusual degree of resistance to infection. Whether the grafts die and are re-placed or go on living, as Mowlem states, is difficult to say from x-ray evidence. Whatever the process may be, the fragmentation results in rapid new bone formation. We have noted the new cortex formation which he describes (Fig. 13c). In 5 instances, ununited

linear fractures were present in relation to a defect and united rapidly after grafting. Two of these in the tibia were united in 2 months (Figs. 3, a, b, c, d, e, f, g). In two instances complete defects were present. One of these

was solid enough for weight bearing after 7½ months, and the patient has been on full activities for 5 months. The other case (Fig. 4, a, b, c, d) is solid at 6 months with obliteration of the defect.

Fig. 4 Case 30, V. G. A complete defect in the tibia following a compound fracture. The sinus shown in b, was infected with *Staphylococcus aureus* and *Bacillus proteus*. Sequestra were present in the defect. The tibia was solid 6 months after sequestrectomy with cancellous bone grafting, as shown in c and d.

TECHNIQUE OF OPERATION

Preoperative and postoperative care. The patient is started on 20,000 units of penicillin intramuscularly every 3 hours, 2 days before operation. This is continued postoperatively until his temperature has remained normal from 2 to 5 days. At operation a pneumatic tourniquet is used to ensure a dry field. This is essential for complete sequestrectomy. Any sinus is injected with methylene blue so that no infected tissue will be left behind. All scar tissue, granulation tissue, and sequestra are removed. The cavity is excised with an osteotome or curetted down to healthy bleeding bone. Where feasible, a block resection of the bone defect is done. The wound is washed out with saline, and penicillin sulfathiazole powder, 100,000 units to 20 grams, is sprink-

led liberally during the operation to ensure that all exposed tissues are protected. The periosteum is stripped as little as possible.

The grafts are taken from the anterior portion of the iliac crest by an assistant and the two fields are kept separate. Both iliac crests are prepared, as the full extent of the cavity cannot be determined from the x-ray picture and is usually much larger than expected. The posterior iliac crest has also been used. The crest is exposed with as little stripping of the periosteum and muscles as possible. The contour of the ilium is maintained. A trap door of cortical bone with attached periosteum is raised from the crest of the ilium. A wedge of cancellous bone (Fig. 5) can then be cut and further bone obtained with a curette. The wedge of cancellous bone is shaved with a sharp osteotome into thin chip grafts. All bone. This is essential as cortical bone has less resistance to infection (Figure 11, a, b, c) demonstrates this point. A previous chip graft was done in England using cortical and cancellous bone from the tibia. The graft was unsuccessful and the cortical sequestra can be seen in the roentgenogram (Fig. 6, a). Cancellous chip grafting was successful (Fig. 6, b and c).

The chips are mixed with the penicillin sulfathiazole powder and packed loosely into the cavity. The bone edges are bevelled and overlapped with chips to increase the surfaces in contact. One of us (J. E. B.) fills the cavity

with chips and penicillin powder held together with coagulated autogeneous plasma. One to 2 cubic centimeters of .02 per cent sterile agar is added as a coagulant. This produces a vehicle of jelly-like consistency fixing the sulfathiazole and penicillin to the fragments. The time of absorption of the penicillin and sulfathiazole is prolonged and the plasma produces more concentrated nourishment for the grafts than blood clot. The skin defect is then closed. If more than a simple plastic procedure is necessary, the operation is completed by a plastic surgeon. The limb is enclosed in a plaster-of-Paris cast, which is not changed for 3 weeks. Soft tissue immobilization is important for healing and the limb must be immobilized until the grafts are consolidated.

This report is necessarily a preliminary one, as the series covers just over a year and many of the cases have been done in the past few months. The final fate of the grafts will have to be evaluated, but to date they have formed good bone with no evidence of absorption with use.

Site of defect. The tibia was involved in 29 cases, the femur in 12, the os calcis in 3, the humerus in 6, the carpus in 2.

In all 52 cases infection was present at the time of operation. Preliminary sequestrec-

tomy was done by us in 6 of these, and many had had a previous sequestrectomy which had not been successful, as sequestra still remained. Three plates, a screw, wire, and numerous foreign bodies were also removed. Sequestrectomy was not done as a separate operation unless the patient was being anesthetized for a preliminary plastic procedure and the defect was readily accessible. In bones clothed by muscle, the extra opera-

tion will increase muscle fibrosis. In the tibia it is likely to increase the skin defect and make subsequent wound closure more difficult. We do not consider that there is anything to be gained by a preliminary sequestrectomy, as the granulating cavity must be curetted again before insertion of the cancellous grafts. Sequestrectomy with preliminary split skin grafting of the cavity which has recently been described (4, 5) would appear to be an unnecessary procedure, with far from assurance of a complete take of the skin grafts and no assurance of the eradication of the infection in the time which elapses before the final bone graft is carried out. Sterilization of the all infected scar, granulation tissue and diseased bone with the aid of penicillin and sulfathiazole. Any failure in the take of the split

skin graft leaves a portal of entry for further infection.

CAUSE OF INJURY AND SOURCE OF INFECTION
The cause of injury and source of infection were as follows:

- | | | |
|---|---|----|
| 1 | Gunshot wounds involving bone | 45 |
| 2 | Compound fractures | 3 |
| 3 | Bone infection following open reduction of simple fractures | 3 |
| 4 | Bone abscesses from childhood osteomyelitis | 2 |

The 2 cases of bone abscess from a blood-borne infection in childhood had had recurrent acute attacks, and both were infected with *Staphylococcus aureus*. Healing occurred without

incident, and there were no symptoms, and the cavities were obliterated (Fig. 7, a, b).

Clostridium	2
Alcaligenes	1
Bacillus coli	1

BACTERIOLOGY

In 21 instances, the infection was a mixed one. Penicillin was given to all patients routinely, despite the presence of penicillin-resistant organisms. Bacteriology in 10 cases was incomplete—either no growth was reported or no report was found. The organisms in their frequencies were:

Staphylococcus aureus	17
Bacillus proteus	11
Diphtheroid bacillus	7
Pyocyanus (Pseudomonas)	7
Hemolytic streptococcus	3
Nonhemolytic streptococcus	3
Escherichia	3
Staphylococcus albus	2
Aerobacter aerogenes	2

In the 4 failures the organisms found were: In case 14, the *Staphylococcus aureus* (resistant to 30 units penicillin per 100 c.c.); in case 19 the *Bacillus proteus* and a clostridium; in case 29 the *Staphylococcus aureus*, *aerobacter*, *pseudomonas*, and *Bacillus proteus*; in case 51 the *Bacillus proteus*.

In these 4 cases, organisms resistant to penicillin were present and were undoubtedly a factor in the failure. In 3 of these further sequestra have been demonstrated, probably due to the interference with the blood supply of relatively avascular bone, plus continuing infection. The other failure was in a cavity surrounded by very sclerotic bone. The chip

SURGERY, GYNECOLOGY AND OBSTETRICS

grafts were later removed and had sequestered with no evidence of osteogenesis. Poor blood supply to the grafts plus penicillin-resistant organisms resulted in failure. No virulent flare-up of infection has resulted from operation in any of the 52 patients.

WOUND CLOSURE AND IMMEDIATE RESULTS

Extensive scarring and sinus formation were present in almost every case. This necessitated some form of plastic closure of the wound in 30 instances. The plastic procedures included local mobilization of the edges, rotation flaps, double-ended local pedicles, 2 abdominal pedicles, and 1 caterpillar flap. In some instances the skin was mobilized completely around the extremity over a wide area. In 33 cases the wounds were perfectly healed at the first change of plaster. Of the remaining 19 all are healed except 2.

The causes of failure of the wounds to be completely healed at the first change of plaster were: persistent sinus to bone in 5, loss of flap or a portion in 3, superficial necrosis of skin edges due to tension in 8, hematoma in 2, and stitch abscess in 1.

The 8 cases in which the superficial dry necrosis occurred could probably have been avoided with more careful closure. These all healed with no infection and minimum scarring. The loss of a flap or a portion did not affect the underlying cancellous grafts. In 1 case in which a complete caterpillar graft was lost (Fig. 8, a, b) the remarkable viability of cancellous chip grafts was demonstrated. None was lost and the cavity has consolidated. To date there has been no reopening of any wound or flare-up of osteomyelitis after healing.

In an additional series of 5 cases in which infected bone defects involved joints (Fig. 6, a, b), the same routine has been carried out. All of these are healed; 3 are firmly arthrodosed and the other 2 have been done too recently to expect arthrodesis.

SUMMARY AND CONCLUSIONS

1. In 52 infected bone defects cancellous chip grafts have been inserted after sequestrectomy and the wound closed, with success in 92 per cent.
2. The method is applicable to traumatic osteomyelitis and some cases in which the infection has been blood-borne.
3. No virulent infections have resulted and there has been no flare-up of infection after healing, for periods up to 14 months.
4. In a small series in which traumatic osteomyelitis involved joints, chip grafts have been used after sequestrectomy with healing and satisfactory fusion.
5. Successful chip grafting in the presence of infection depends upon (a) complete sequestrectomy and removal of all infected tissue; (b) an adequate vascular bed for the grafts which must have all cortex removed; (c) no dead spaces, (d) penicillin, systemically and locally, with sulfathiazole, as indicated; (e) full thickness skin to close any skin defect; (f) plaster immobilization (for soft tissue healing and until the bone is consolidated).
6. The one stage method for obliterating infected bone defects saves months of hospital treatment and restores function before disuse changes become irremediable.

OUTLET PELVIMETRY

A Commentary, and the Presentation of a Pelvimeter for Measuring the "Symphysis and Sacral Biparietal Distance"

HERBERT THOMS, M.D., New Haven, Connecticut

THE measurement of pelvic outlet diameters has always presented certain difficulties, whether the attempt to determine these dimensions has been by manual or roentgenological means. In the former case, because of a lack of definite palpable end points for the intertuberal or transverse diameter, the estimation of this dimension may be quite variable in the same individual even when measured by experienced observers. Roentgenologic methods for depicting the pubic arch have not proved very satisfactory because of distortion difficulties. Lateral pelvic views, nevertheless, are very useful in determining anteroposterior diameters and relationships. However, important morphological data can be obtained

by either method, manual methods being particularly valuable in determining the shape and general size of the pubic arch.

The pelvic outlet in relation to labor presents a mechanism which it is useful to consider. With a normally shaped pubic arch with adequate capacity the head extends with the occiput in close contact with the subpubic angle. The arc described by the extending sinciput is minimal under these circumstances and the likelihood of perineal damage is also minimal (Figs. 3 and 4).

However, when the subpubic angle is narrow and the capacity of the arch is thereby lessened, the head as a whole is forced backward, the biparietal diameter engaging the ischiopubic rami; the arc of the extending sinciput is lengthened, and the liability of soft tissue damage thereby increased. It is obvious, therefore, from the mechanics of

From the Department of Obstetrics and Gynecology, Yale University School of Medicine.

SURGERY, GYNECOLOGY AND OBSTETRICS

Fig. 3. With the head flexed at the perineum before extension and disengagement take place the occipital part of the head comes in contact with the pubic arch, meeting resistance at the parietal bosses (Fig. 4) (Modified from DeLee.)

Fig. 4. When the fetal head begins to extend the parietal bosses meet resistance at B-B, and point A sweeps upward over the perineal floor. (Modified from DeLee.)

these head and outlet relationships that the width of the subpubic angle and the shape of the pubic arch are of considerable importance. As Allen logically states, "The important point is clearly how close the occiput is allowed to approach the lower edge of the symphysis." If we consider variations in the downward course of the pubic rami, it becomes evident that the degree of the pubic angle in itself may

Figs. 5 and 6. The pubic angles and bituberal distances are identical. The pubic arches, however, have important differences from the obstetrical viewpoint.

Fig. 7. The sliding crossbar of a Thoms outlet pelvimeter has been replaced by a solid bar 9 centimeters in length. After palpation of the arch this bar is brought to fit snugly between the rami. It is held in this position while the arm of the pelvimeter is placed at the lower edge of the symphysis. The symphysis biparietal distance is measured by holding the cross-bar in position and swinging the arm posteriorly to the sacrococcygeal junction—1 centimeter is deducted from the reading to compensate for the thickness of the lower sacrum (Modified from Williams.)

Fig. 8. The pelvic inlet: A, anteroposterior diameter, B, transverse diameter, C, posterior sagittal diameter, D, transverse diameter of midplane.

Fig. 9. Anteroposterior diameters seen in lateral aspect: A, anteroposterior diameter of inlet, B, posterior sagittal diameter of inlet, C, anteroposterior diameter of midplane, D, posterior sagittal diameter of midplane, E, sacral-biparietal distance, F, symphysis-biparietal distance.

not give a good index to outlet capacity and may even be misleading. Figures 5 and 6 illustrate this point. In both instances identical pubic angles are shown with the same intertuberal diameters, yet the available space in the upper part of the two arches is quite different.

As an alternative to determining the subpubic angle and attempting to determine a transverse outlet diameter, the measurement of the symphysis-biparietal distance has been recommended by Allen. This is the distance within which a normal biparietal diameter cannot approach the lower edge of the symphysis. This author determines this dimension from a roentgenographic film, but I am convinced that equally good information can be determined adequately by the palpatory method here described. Because of the difficulties previously commented upon of measuring the bituberous diameter, I find myself quite in agreement with this same author, who says "The bituberous diameter between the inner surfaces of the ischial tuberosities has also been discussed previously and the conclusion was then reached that this diameter could not satisfactorily be measured by any method so far described. The diameter, furthermore, is not of great importance *per se*, except in so far as it represents the free posterior end of the pubic arch: contraction of the arch always means a reduction in the intertuberos diameter, and since the arch can be more accurately measured, there seems to be little point in measuring the bituberous." From the roentgenological determination of

the symphysis-biparietal distance. Allen recommends a special film using Chassard and Lapine's technique. He uses 10 centimeters as representing the normal biparietal distance, a figure slightly larger than the average of 93 millimeters given by Seammon and Calkins. In the pelvimeter here presented I have used a crossbar of 9 centimeters, allowing thereby about 0.5 centimeter for the thickness of the soft parts covering the pubic rami in their medial aspect.

METHOD

The patient is brought well down over the edge of the examining table in the lithotomy position; the arch is thoroughly palpated, by using both hands simultaneously as in the manner well described in textbooks. The course of the rami downward is noted, whether straight, moderate, or widely arcuate. The crossbar of the pelvimeter is then passed between the rami, and by upward pressure it is brought as near the symphysis as possible. As the crossbar is held in this position, the end of the arm of the pelvimeter is brought to the lower edge of the symphysis and the symphysis-biparietal distance read on the scale as shown (Fig. 7).

Another outlet dimension which should prove useful is the sacral-biparietal distance; that is, the distance from the lower terminus of the symphysis-biparietal distance, as described, to the tip of the sacrum. This can be measured externally with the pelvimeter or it can be determined satisfactorily on the lateral film used in the general pelvic survey. This is

SURGERY, GYNECOLOGY AND OBSTETRICS

accomplished by measuring downward between the shadows of the descending pubic rami the symphysis-biparietal distance previously determined. From the lower terminus of this distance to the tip of the sacrum represents the sacral-biparietal distance. The author is aware that the shadows of the pubic rami do not lie in the same plane and that the mean distance between them probably does not exactly represent the sagittal plane of the body. However, if films are taken at a target-film distance of 36 inches as recommended, the error encountered would not be obstetrically significant. For a further discussion of this aspect of roentgen pelvimetry the reader is referred to the author's views published elsewhere (3).

It might be useful to consider the relationship of these proposed outlet dimensions to a general pelvic survey. Such a survey for determining the adequacy of the bony pelvis for childbearing should include roentgen and palpatory methods (4). The former should include two flat films, one showing the birth canal from above downward, from which certain inlet and midplane measurements may be determined, and a second film taken laterally from which certain inlet, midplane, and outlet measurements may be obtained. The importance of morphological characteristics should also be emphasized in any such survey and, in addition, the following pelvic measurements will give useful information (Figs. 1, 2, 8, 9):

Pelvic inlet—Anteroposterior, transverse, posterior sagittal diameters

Pelvic midplane—Anteroposterior, transverse, posterior sagittal diameters
 Pelvic outlet—Symphysis-biparietal, sacral-biparietal distances
 In conclusion, the author takes this opportunity to mention again that the technical cost of such a pelvic survey need be hardly more than many hospital laboratory procedures, and that the information thus obtained is so greatly useful that every primigravida woman should have its benefit.

SUMMARY

1. Pelvic outlet pelvimetry at present is not satisfactory because transverse dimensions cannot be accurately determined.
2. The important information in a given case should reveal how close will be the approach to the lower edge of the symphysis of the biparietal diameter of the child's head as it passes through the pelvic arch.
3. This information may be secured by palpation, and with the pelvimeter here described.
4. The comprehensive pelvic survey should include inlet, midplane, and outlet dimensional information, by use of both palpatory and roentgen methods. Prognosis on the information so obtained should be solely the responsibility of the obstetrician.

THE ABSORBABLE HEMOSTATIC AGENTS

THE absorbable hemostatic agents which have been recently developed, such as fibrin foam, oxidized cellulose (cellulosic acid), and gelatin sponge, represent a helpful contribution to the technique of surgery. Until these materials became available, muscle had been used as a hemostatic agent by the neurosurgeons since its introduction by Cushing in 1911. Most of the clinical experience with these new hemostatic agents, especially the fibrin foam and gelatin sponge, has been in neurosurgery. These reports have stimulated an interest in utilizing these materials to meet the varied problems of hemostasis in general surgery. Enough data are now available and more will soon be published which establish the usefulness of these agents in the broad field of surgery.

The fundamental mechanism involved in the use of the hemostatic agents is to hasten

the formation of a clot and give structural support to the clot. This permits control of hemorrhage of a greater magnitude than could be expected from the normal protective mechanism—the physiological process of the clotting of blood. In using hemostatic agents one is merely enhancing the value of a protective mechanism of the body.

The particular field of usefulness of the hemostatic agents is in the control of hemorrhage where ligature or suture is not adequate or feasible. *There is no place for controversy over the matter of using these materials in lieu of ligature or suture in the ordinary routine technique of surgery.*

In dissecting away scar tissue, freeing adhesions, or in mobilizing large flaps one may have a continuously oozing surface which may be difficult to control except by these agents. In the first aid treatment of hemorrhage from surface wounds, especially from large veins, these materials should be very helpful as a temporary expedient until the patient can be cared for in an adequately equipped operating room. In hemorrhage from parenchymatous organs, such as in wounds or resections of the liver, there is a place for better hemostasis than can be obtained by ligature or suture alone. This is also true for the bleeding from the under surface of the liver after cholecystectomy.

One may encounter a sudden venous hemorrhage during the course of an operative procedure, such as in the mobilization of an organ or tumor, where the bleeding point cannot be identified for application of a hemostat because of the massive bleeding or the inadequacy of the exposure. In such trying situations the hemostatic agents offer an alterna-

tive to the blind application of hemostats which may damage adjacent vital structures or fail to prevent exsanguination. It has been customary in the past to resort to large gauze packs in an attempt to control such bleeding. When these packs are subsequently removed one may again encounter hemorrhage. In using the absorbable hemostatic materials one does not have to contend with this problem.

In operations on the bile ducts or in resections of the pancreas one may open the portal vein. If vein suture is not feasible the only alternative is ligation, which of course is most undesirable. In such circumstances, as well as in injury to other veins which one may not choose to ligate and where vein suture may not be feasible, the hemostatic agents may offer an alternative which may prove most helpful. In an experimental study one of these agents has been used to control hemorrhage from the vena cava of animals by the application of a "patch" such as is used by the neurosurgeons in dealing with hemorrhage from the dural sinuses. It is desirable in this "patch" technique on veins to cover the hemostatic agent with a layer of tissue such as the peritoneum or pleura to prevent dislodgment even though the "patch" may become quite firmly adherent to the vein within twenty to thirty minutes. If vein suture is feasible in an injury to a large vein there is also a place for the hemostatic agents as a secondary line of defense against leakage and hematoma formation.

Only a few of the situations where the absorbable hemostatic agents may be helpful have been outlined. The entire field of surgery abounds with problems which may be aided by these materials. For example, experimental studies are being conducted to ascertain their usefulness in the control of hemorrhage from the heart and the aorta where they may possibly have some value.

The several hemostatic agents have different physical properties and some variation in the rate of absorption. The fibrin foam and the gelatin sponge are similar in that they are a spongy material. The oxidized cellulose has the texture of ordinary gauze or cotton. In the dry state the fibrin foam is brittle and easily fragmented, whereas the gelatin sponge can be compressed by the fingers into a pliable sheet. The fibrin foam may be slightly stronger than the gelatin sponge when moistened. Under favorable conditions the fibrin foam or the gelatin sponge undergo absorption within about four to five weeks. The oxidized cellulose is absorbed more rapidly. In the presence of infection the gelatin sponge may become liquefied and disappear within a few days to a week. When oxidized cellulose comes in contact with blood it turns brown and then black. Fibrin foam or gelatin sponge take on a pink or red color when blood is taken up by the myriads of interstices.

There is as yet relatively little information to guide one in the selection of the agent best suited to a particular hemostasis problem in general surgery. As more clinical and experimental data become available it may be possible to work out a recommendation to cover the various situations in which one hemostatic agent may have more value than another.

There will undoubtedly be other absorbable hemostatic agents developed which may have properties that will be more useful for some of the hemostasis problems than the material now available. There is a place for a tougher and stronger spongy material as well as a place for a more rapidly absorbed spongy or foamy material, and possibly a more slowly absorbed material than is now at hand. This brings up the point that some official supervision should be given to the manufacture of the hemostatic agents so that standardization of absorption properties and sterility controls can be estab-

lished. It would be appropriate for a committee of the American College of Surgeons to make some recommendation on this.

Technical points which can best be described as "know how" but which cannot be easily put into words or diagrams, are essential for the successful use of these materials. One must gain some personal experience in handling these agents before attempting to use them for the control of a severe hemorrhage. The most important general feature of the technique of applying these materials is to permit fresh blood to soak into them and then apply firm even pressure over the bleeding area for from three to five minutes or longer, depending on the magnitude of the hemorrhage and the structure from which it comes. In some instances the hemorrhage may be controlled in less than a minute.

Thrombin solution has been used with these hemostatic substances to hasten the clot formation. Those who have used the fibrin foam and the gelatin sponge recommend soaking these agents in the thrombin solution before applying to the bleeding area. Some have used thrombin solution for soaking the oxidized gauze before use. According to one who has had the widest experience with oxidized cellulose the thrombin is not necessary or even desirable, as the best hemostatic effect is obtained by applying the material in the dry state. This is apparently due to the slightly acid reaction of the oxidized cellulose. Thrombin has been found to be ineffective in an acid medium. If one uses an alkaline solution for the sake of the activity of the thrombin, the particular hemostatic action of the cellulose which is a property of the acidity of the material is thereby negated. Some recent experimental work with gelatin sponge has demonstrated that it has excellent hemostatic properties *per se*. It may be used by soaking only in a physiological saline solution, and then ex-

pressing the excess saline. It may also be used in the dry state if it is first compressed in the fingers until it becomes pliable. If there is any defect in the normal clotting mechanism, such as a deficiency in prothrombin or platelets, it would be necessary to use a thrombin solution. In spite of this evidence on the hemostatic properties of the sponge without thrombin, it would probably be preferable to continue using the thrombin solution with gelatin sponge until further studies clarify the effectiveness of the thrombin in the hemostatic action of these materials.

When pressure is applied to these hemostatic agents after they have been saturated with fresh blood there is a tendency for the spongy material to adhere to the tissues to which it is applied, thus sealing off the hemorrhage. If the blood clots in the spongy material before the pressure is evenly applied or if a hematoma develops under the material it does not tend to adhere firmly and the bleeding may not be controlled. Under such circumstances it is better to try a fresh sponge and attempt to get more even pressure over the bleeding area.

The one most important limitation to these absorbable hemostatic agents is that one should not expect to put large amounts of these materials into wounds, especially if there is contamination or infection present, without having some undesirable sequelae. When any new substance is used in surgery there are bound to be misuses which may reflect unfavorably on the material. The fundamental principle of minimizing the amount of foreign material in a wound applies to the hemostatic agents as well as to anything else. Therefore it is important to minimize the amount of hemostatic agent used and especially to employ as thin a layer of the agent as is compatible with obtaining satisfactory hemostasis. Where there is a massive hemorrhage

which might otherwise be fatal, the amount of material used is of course a minor consideration. When there is trivial bleeding which might cause an undesirable but not necessarily fatal hematoma, then one must weigh the problem of the disadvantages of a foreign material against the disadvantages of a hematoma.

The hemostatic agents are still in an experimental stage of development and clinical use. However, they are destined to have an important place in the armamentarium of the general surgeon as they have had for the neurosurgeon, and will necessarily constitute

some part of the training program of the surgeon, the technical importance of which may be second only to the selection and use of ligatures and sutures.

The judicious use of the absorbable hemostatic agents will make for a greater degree of safety by minimizing blood loss in operative surgery, and furthermore may contribute to a widening of the scope of surgery, especially in the operative attack on malignant tumors in which the results being currently obtained by the accepted operative procedures on some organs leave much to be desired.

HILGER PERRY JENKINS.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE excellent monograph *Diseases of the Adrenals*¹ by Louis J. Soffer reviews completely the physiology and diseases of the adrenals. The chemical and mechanical techniques used in the diagnosis of adrenal disease, the recent methods used in studying the physiology of the glands, and the relation to other glands are discussed.

A detailed study is made of Addison's disease and of its treatment. The preoperative and postoperative treatment of surgical complications in Addison's disease are discussed. While pregnancy is strongly contraindicated in Addison's disease, the interruption of it is condemned as less safe than the attempt to carry it to termination. Advice is given for management.

The unusual sensitiveness of patients with Addison's disease to morphine, codeine, paraldehyde, bromides, barbiturates, insulin, thyroid extract, and thyroxin is emphasized. Epinephrine, sulfonamides, and penicillin may be used as in other patients.

An interesting paragraph is the summary of the experimental treatment of Addison's disease by transplantation of adrenal tissue. This should give successful results with improvements in transplantation technique, and would seem to be the ideal replacement therapy of the future.

The adrenogenital syndrome is also presented with critical discussion of virilism, Cushing's syndrome, adrenal cortical hyperplasia, and adrenal cortical tumors. The therapeutic measures include the use of various hormones, irradiation therapy to the pituitary and adrenals, and surgery.

The medullary and other extracortical adrenal tumors, especially the pheochromocytoma are adequately discussed in this monograph, and the preoperative and postoperative treatment of the various types of tumors are clearly outlined.

It is a well written, concise, and practical book with an exceptionally complete bibliography. It can be recommended to clinicians and all those interested in the physiology of the adrenals.

ARTHUR J. ATKINSON.

IN four hundred odd pages, illustrated by seventy-two well chosen plates, Guthrie's *A History of Medicine*² covers the history of medicine in a distinctly interesting fashion. The volume is well documented

with footnotes and a short list of authoritative publications follow each chapter. An appendix, containing a classified bibliography of medical history with a short evaluation of the more important ones, and a good index are included. Slightly more than half of the volume is devoted to the period ending with the 18th century. The 19th and 20th centuries are complete except that the author has chosen to leave for the evaluation of future historians the most recent advances in medicine and the work of those leaders who are still among the living.

While less exhaustive than Garrison's *Introduction to Medical History*, this volume has succeeded in combining broad philosophical discussion with brief biographical sketches in such a skillful manner as to encourage continuous reading. For the purpose of introducing the medical student to the study of medical history and for reviving the interest of the busy doctor in the fascinating story of medical progress, this volume is highly recommended. The experience of reviewing it has been a wholly enjoyable one.

THOMAS C. DOUGLASS.

THE second edition of *Clinical Electrocardiography*³ by Scherf and Boyd is, as pointed out by the authors, primarily for the advanced student of electrocardiography and not for the beginner. It is well printed and there are only a few typographical errors. The electrocardiograms used as illustrations are numerous and for the most part satisfactory. Much of the text is used in discussing and explaining these cardiograms.

The authors adhere fairly well to the terminology recommended by the American Heart Association. They consider many clinical and controversial subjects and their approach to these subjects is stimulating. The discussion on interference dissociation and parasystole is well written. It would seem that more space could have been given to the subject of precordial leads and to coronary occlusion. The author's remarks regarding the changes incident to hypo-ovarianism will probably be challenged by some authorities.

This 259 page book is a definite contribution to the literature on this subject. It is to be recommended for the reference library of all physicians interested in electrocardiography.

CORRESPONDENCE

THE Rh FACTOR—SEROLOGIC BACKGROUND AND CLINICAL APPLICATION.

—A Correction.

To the Editor: In the paper concerning the Rh Factor appearing in the June, 1946, issue of SURGERY, GYNECOLOGY AND OBSTETRICS, the sentence beginning on the eleventh line from the bottom of the

page, in the right column of page 744, is misleading in that it states: "An individual whose blood is Rh-negative and who carries both Rh-positive and Rh-negative genes is heterozygot." The sentence should, of course, begin "An individual whose blood is Rh-positive . . .", as the presence of Rh-positive genes inevitably means that the individual's blood must be Rh-positive.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

W. EDWARD GALLIE, *Toronto, President*

IRVIN ABELL, *Louisville, President-Elect*

Committee on Arrangements

THOMAS E. JONES, *Chairman*; JOHN W. HOLLOWAY, *Secretary*

CLINICAL CONGRESS TO BE HELD IN CLEVELAND DECEMBER 16 TO 20

THE thirty-second Clinical Congress of the American College of Surgeons, originally planned for New York from September 9 to 13 but postponed because of overlapping with the United Nations Assembly which will overtax hotel facilities, has now been scheduled for Cleveland, Ohio, from December 16 to 20. The change in place was necessary because suitable accommodations were not available in New York during the remainder of this year.

Cleveland has in its Public Auditorium superb facilities for the holding of most of the sessions and for the technical and educational exhibits. Certain official meetings, some of the panel discussions, and a few conferences, will be held in the Cleveland and Statler hotels where excellent accommodations are available. A clinical program in the Cleveland hospitals and Western Reserve University School of Medicine is also being developed by the Committee on Arrangements of which Dr. Thomas E. Jones is Chairman and Dr. John W. Holloway is Secretary.

This will be the first time that Cleveland has been host city to the Clinical Congress. A meeting was planned there in 1942 after the United States Army took over the Stevens Hotel in Chicago where the Congress had originally been scheduled. Later there was an announcement that the Cleveland Public Auditorium would also be needed by the War Department, and the 1942 Clinical Congress was voluntarily cancelled because of this and other war conditions.

Cleveland convention and hotel officials express great interest in the Clinical Congress as a contribution to the city's educational and scientific advancement. The Fellows are assured of a most congenial atmosphere in which to meet. The

American College of Surgeons is well known and highly esteemed in Cleveland, as is natural in the home city of one of its most eminent founders, the late George Crile, Chairman of the Board of Regents for several years, and of many other honored Fellows, who have labored to develop the medical school and hospitals into maximum effectiveness in service to the sick and injured.

Cleveland has twenty-one hospitals approved by the American College of Surgeons. In several of these, operative and nonoperative clinics and demonstrations will be arranged during the week of the Congress. The preliminary clinical program will be published in a later issue.

As for the program that had been planned for New York for the scientific sessions, hospital conferences, and other events except clinics, this will be carried out in Cleveland with few, if any, changes. Up to the time of going to press there has not been opportunity to receive replies from all of the speakers who have been asked whether the change of time and place will affect their acceptance, but most responses have been in the affirmative, indicating that the program as outlined in succeeding pages will stand.

There is keen appreciation of the work done by the New York committee in preparing the clinical program there. While it cannot be used this year, it is hoped that it can be carried out at the 1947 Clinical Congress in New York.

FIRST POSTWAR CONGRESS

Following the same plan developed for the New York meeting, this first postwar Clinical Congress will differ from the meetings for several years prior to the war in that a return will be made to the original custom of holding the Presidential Meet-

ing on the opening evening, Monday, and the Convocation on the final evening, Friday, instead of combining them on the first night. This separation is especially desirable this year since exceptional interest will be centered on the Convocation as a result of the participation in the ceremonies of classes from 1942 through 1946.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening in the Music Hall of the Cleveland Public Auditorium. It will begin with the impressive processional of the officers, regents, and honorary guests. Dr. Thomas E. Jones, Chairman of the Committee on Arrangements, will give the address of welcome. Dr. W. Edward Gallie of Toronto, President of the College, will preside and will deliver the Presidential Address. An inaugural ceremony will be held for the incoming officers: Dr. Irvin Abell of Louisville, President; Dr. Leland S. McKittrick of Boston, First Vice-President; and Dr. F. Phinizy Calhoun, Atlanta, Second Vice-President. Foreign guests will then be introduced.

The first Martin Memorial Lecture will be a new feature to be included in the Presidential Meeting this year. The invitation to give this lecture has been accepted by Dr. Edward D. Churchill of Boston. This lectureship was established upon motion of the Board of Regents at its mid-year meeting on April 1, as a memorial to both Dr. Franklin H. Martin and Mrs. Martin. The founder of the College and of SURGERY, GYNECOLOGY AND OBSTETRICS was joined by his wife in making the College the beneficiary at their deaths of the Journal, together with its physical plant operated by the Surgical Publishing Company of Chicago, of which they were the owners. Doctor Martin died in 1935 and Mrs. Martin in 1945.

The Martin Memorial Lecture, to be given annually during the Clinical Congress, and dealing with a scientific subject of the author's choosing, will supplant the Annual Oration in Surgery.

CONVOCATION

The Convocation scheduled for Friday evening, will open with a processional of officers, regents, and governors. The President, Dr. Irvin Abell, will preside and will make the opening remarks, confer the honorary fellowships, and present the candidates for fellowship.

An Assembly of Initiates will be held prior to the Convocation on Friday in order to instruct them in the Convocation procedure and other matters. On this occasion the initiates will sign the fellowship roll.

Several hundred surgeons who have been received into fellowship *in absentia* during the years in which no Convocation was held, will be added to the number of initiates for the current year who will be present to participate in the initiation ceremonies.

SCIENTIFIC SESSIONS

General Surgery

Eminent surgeons and specialists, recognized as authorities in their fields, will address the scientific sessions, to be held on Tuesday, Wednesday, and Thursday evenings. These will be conducted as symposia, and the subjects for the three nights will be as follows: Tuesday, "Care of the Patient Before and After Operation"; Wednesday, "Venous Thrombosis and Prevention of Pulmonary Embolism"; and Thursday, "Antibiotic and Chemotherapeutic Agents in Surgery." The annual Fracture Oration will be included in the Wednesday evening program.

Two major panel discussions will be held every afternoon except Thursday when the first panel will be omitted because of the annual meeting of the Fellows.

A symposium on fractures and other traumas will be held on Tuesday afternoon, and a symposium on cancer on Wednesday, from 2:00 to 4:00 o'clock.

Concurrent panel discussions are also planned on Friday afternoon for each of the following specialties: plastic surgery, thoracic surgery, urology, neurological surgery, orthopedics, and obstetrics. Outlines of the programs are published in succeeding pages.

Ophthalmology and Otorhinolaryngology

Ophthalmology panel discussions will be held Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock on, respectively, "Retinal Detachment," "Glaucoma," and "Keraplasty." On Tuesday evening at 8:00 o'clock there will be a symposium on "Orbital Reconstruction Including Prosthesis." On Thursday evening a scientific session is planned with the following as the subjects: "Recent Advances in Ophthalmology"; "Medical Treatment of Glaucoma"; and "Visual Disturbances Associated with Head Injuries."

Otorhinolaryngology panel discussions will be held Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock on, respectively, "Treatment of Ménière's Disease," "Osteomyelitis of the Skull," and "Rehabilitation of War Deafness." On Tuesday evening at 8:00 o'clock there will be a symposium on "Treatment of Deafness" and on Thursday evening a symposium on "Surgery of the Nasal Accessory Sinuses."

Of interest to ophthalmologists, otorhinolaryngologists, and other surgeons will be a symposium to be held on Wednesday evening at 8:00 o'clock on "Plastic Surgery of the Head and Neck."

FORUMS ON FUNDAMENTAL SURGICAL PROBLEMS

The Forums on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday, and Friday mornings. Included in them will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned, but questions and comments will be invited. Especially keen interest is expected in these sessions this year because of the accumulation of the results of 5 years of work since the last Clinical Congress. Dr. Owen H. Wangenstein of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the forums, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

HOSPITAL CONFERENCE

Dr. W. Edward Gallie, President of the College, will address the opening session of the twenty-fifth annual Hospital Standardization Conference on Monday morning at 10:00 o'clock in the Auditorium; and will preside at the meeting, which will be attended by surgeons and hospital representatives. Following Dr. Gallie's résumé of the Hospital Standardization program of the College, including plans for the future, there will be reports on the progress of the 1946 Hospital Standardization survey, final results of which, including the Approved Lists of hospitals, cancer clinics, and approved hospitals for graduate training in surgery, will be announced at the end of the year, instead of at the Clinical Congress as was the practice in former years.

The remainder of the Monday morning session will be devoted to talks by medical and hospital authorities on advances in medicine and surgery as they affect the postwar hospital, with particular consideration of their relation to the Hospital Standardization program.

The afternoon conference on Monday will be concentrated upon current problems and the outlook for the future in nursing service. The Tuesday morning conference will have as its main sub-

ject personnel management, and the Tuesday afternoon session will be centered around personnel problems in specific fields, such as dietary, laboratory, medical records, medical social service, x-ray, physical and occupational therapy, and other professional and semi-professional services. The discussions will emphasize the importance of scientific management techniques in assuring high quality service from personnel.

The Wednesday morning conference will have as its main theme the importance of assuring high standards of care to the community and patients through providing in the general hospital facilities for all types of illness. The subject will be discussed from the standpoint of psychiatric, tuberculous, cancer, chronically ill, and convalescent patients. The Wednesday afternoon conference will center mainly around discussion of ways of improving co-operation between general hospitals and special hospitals in the care of all types of special patients.

The Thursday morning conference will revolve around the physical plant of the hospital and the importance of improvement and modernization in raising standards of care of the patient. New mechanical and technical developments will be presented. The afternoon conference will discuss the hospital as the health center of the community, with consideration of the effects of this concept upon hospital public relations and upon the progress of preventive medicine and public health.

An evening conference will be held at 7:30 o'clock on Tuesday. This will be devoted to discussion of the responsibilities of trustees, and members of governing boards will be especially invited to attend and to participate. A conference will be held on Wednesday evening also. This will be a round table conference on responsibilities of hospital administrators, and the preparation which is necessary to enable them to cope successfully with the wide range of administrative problems. The discussion of these problems will interest all hospital personnel.

ANNUAL MEETING OF FELLOWS

The annual meeting of the Governors and Fellows will be held on Thursday afternoon at 1:45. There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization, and to learn how it has not only raised the professional and ethical standards of surgery, but has also promoted good hospitalization and general improvement in the practice of medicine in the United States and Canada. Each Fellow has a

personal part in this work and may extend the influence of the College materially in his local community. Hospital Standardization alone offers him unlimited opportunity to provide better medical care for his patients in the hospital in which he works through continuous progress in applying the principles of the Minimum Standard which insure the best care of the patient.

Every Fellow will want to attend this important meeting, at which reports will be presented on financial affairs; Hospital Standardization; Graduate Training in Surgery; Medical Motion Pictures; Publications; Public Relations. Library and Literary Research; the work of the state and provincial credentials committees, committees on applicants, and the Committee on History Reviews; Sectional Meetings, 1946; and the Department of Clinical Research, including cancer clinics, Medical Service in Industry, the Committee on Cancer, and the Committee on Fractures and other Traumas. Dr. Abell will report on administration of the College, staff changes, and retirements, and Dr. Arthur W. Allen, Vice-Chairman of the Board of Regents will discuss "Fellowships, Obligations and Opportunities."

STATE AND PROVINCIAL EXECUTIVE, CREDENTIALS AND JUDICIARY COMMITTEES

On Wednesday morning from 9:00 to 12:00 o'clock the State and Provincial Executive, Credentials, and Judiciary committees will meet to discuss their respective activities.

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily. These are a much appreciated feature of the Clinical Congress. Despite the decrease in production of such films during the war period, a surprising number of new pictures on varied subjects are being received by the American College of Surgeons for review.

The schedule will be so arranged as not to conflict with either the clinical program at the hospitals or the scientific sessions. Both sound and silent, standard and color films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be held in the Cleveland Public Auditorium. Leading manufacturers of surgical instruments, x-ray apparatus,

sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, pharmaceuticals, and publishers of medical books will be represented in the exhibition. The technical exhibits will demonstrate many of the newer features learned from our experience in the war.

ADVANCE REGISTRATION

The hospitals of Cleveland afford accommodations for a considerable number of visiting surgeons. However, in order to insure against overcrowding, attendance at the Congress will be limited to the number that can be comfortably accommodated at the meetings and also by accommodations in the hotels. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

Fellows of the College whose dues are paid to December 31, 1945, initiates of the classes of 1947, through 1946, and Fellows in military service will not be required to pay a registration fee for the Clinical Congress in Cleveland. Checks that have already been sent for the New York Congress are being returned. For endorsed junior candidates the fee is \$5.00. Surgeons, not Fellows, who attend as invited guests of the College, will pay a registration fee of \$10.00.

CLEVELAND HOTELS AND THEIR RATES

Although the hotel situation in Cleveland seems more favorable than in many other cities, it is nevertheless essential to make reservations as far in advance as possible. Following is a list of the principal hotels:

	No. of Rooms	Rates
The Alcazar, Surrey and Derbyshire Roads	200	\$3.00 up
Hotel Allerton, E. 13th St. & Chester Ave.	600	2.65 up
Hotel Auditorium, E. 6th & St. Clair Ave.	300	2.00 up
Belmont Hotel, Euclid Ave. at E. 40th St.	200	2.00 up
Hotel Bolton Square, Carnegie at E. 89th St.	300	1.50 up
Carter Hotel, 1012 Prospect Ave.	600	4.00 up
Hotel Cleveland, Public Sq. & Superior Ave.	1,000	3.00 up
Fenway Hall Hotel, Euclid Ave. at Univ. Circle	400	3.00 up
The Hollenden, Superior Ave. at E. 6th St.	1,000	3.00 up
Lake Shore Hotel, 21506 Edgewater Dr.	450	3.50 up
New Amsterdam Hotel, Euclid Ave. at E. 22nd St.	300	2.00 up
Hotel Olmsted, E. 9th St. & Superior Ave.	250	3.00 up
Park Lane Villa, E. 105th & Park Lane Ave.	400	3.00 up
Sovereign Hotel, 1575 E. Blvd.	300	2.50 up
Hotel Statler, Euclid Ave. at E. 12th St.	1,000	3.00 up
Tudor Arms Hotel, Carnegie at E. 107th St.	200	3.50 up
Wade Park Manor, E. 107th & Park Lane	400	3.50 up
The Westlake, Blount St., Rocky River.	400	3.00 up

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday

- 10:00 General Assembly for Surgeons and Hospital Representatives
 1:30-3:00 Panel Discussion
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference
 1:00 Surgical Film Exhibition (General)
 3:30-5:00 Panel Discussion
 8:00 Presidential Meeting

Tuesday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 10:00 Hospital Conference
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 9:30-12:00 Forum on Fundamental Surgical Problems, 10:00 Surgical Film Exhibition (General)
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 1:30-3:00 Panel Discussion
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference
 2:00 Symposium on Fractures and Other Traumas
 2:00 Surgical Film Exhibition (General)
 3:30-5:00 Panel Discussion
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 7:30 Hospital Conference—Trustees
 8:00 Scientific Session, General Surgery
 8:00 Scientific Session, Ophthalmology
 8:00 Scientific Session, Otorhinolaryngology

Wednesday

- 8:00 Meeting of Cancer Committee
 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected Local Hospitals
 9:30 Hospital Conference
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 9:30-12:00 Forum on Fundamental Surgical Problems, 10:00 Surgical Film Exhibition (General)
 State and Provincial Committees:
 9:30 Judiciary Committees
 10:00 Executive Committees
 10:30 Credentials Committees and Committees on Applicants
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 12:00 Meeting of Board of Governors
 1:30-3:00 Panel Discussion
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Symposium on Cancer

- 2:00 Surgical Film Exhibition (General)
 2:30 Hospital Conference
 3:30-5:00 Panel Discussion
 6:00 Vandyck Reunion Dinner
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 7:30 Hospital Conference
 8:00 Scientific Session, General Surgery
 8:00 Scientific Session (Eye, Ear, Nose and Throat)

Thursday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Hospital Conference
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 9:30-12:00 Forum on Fundamental Surgical Problems
 10:00 Surgical Film Exhibition (General)
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 1:30 Adjourned Meeting, Governors
 1:45 Annual Meeting, Fellows
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference
 3:00 Panel Discussion—Graduate Training in Surgery,
 3:30-5:00 Panel Discussion
 3:30 Surgical Film Exhibition (General)
 3:30 National and Regional Fracture Committees,
 4:00 Committee on the Library
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 8:00 Scientific Session, General Surgery
 8:00 Scientific Session, Ophthalmology
 8:00 Scientific Session, Otorhinolaryngology,

Friday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
 9:30-12:00 Forum on Fundamental Surgical Problems
 10:00 Surgical Film Exhibition (General)
 1:30-3:00 Panel Discussion, Surgery of the Stomach
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00-4:00 Panel Discussions
 Obstetrics
 Plastic Surgery
 Neurological Surgery
 Thoracic Surgery
 Urology
 Orthopedic Surgery
 2:00 Surgical Film Exhibition (General)
 3:30-5:00 Panel Discussion, Surgery of the Vascular System.
 8:00 Convocation

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY

Tuesday

Care of the Patient before and after Operation

Fluid and Electrolyte Balance. CARL MOYER, Eloise, Michigan.

Nutritional Preparation of the Substandard Risk Patient. RICHARD L. VARCO, Minneapolis.

Use of Blood and Blood Substitutes. JOHN D. STEWART, Buffalo.

Blood Transfusion Problems, with Special Reference to the Rh Factor. ALEXANDER S. WIENER, Brooklyn.

Safe Conduct of the Patient Through Operation. OWEN H. WANGENSTEEN, Minneapolis.

Wednesday

Venous Thrombosis and Prevention of Pulmonary Embolism

Interruption of Deep Veins. ARTHUR W. ALLEN, Boston.

Sympathetic Nerve Block. ALTON OCHSNER, New Orleans.

Anticoagulants. D. W. GORDON MURRAY, Toronto.

Fracture Oration

Modern Methods in the Treatment of Fractures. EDWIN W. RYERSON, Chicago.

Thursday

Antibiotic and Chemotherapeutic Agents in Surgery

Pathologic Physiology of Surgical Infections. JOHN S. LOCKWOOD, New Haven.

Penicillin—Its Use in Surgery and Influence on Earlier Types of Chemotherapy. WILLIAM A. ALTMEIER, Cincinnati.

Streptomycin. HORTON C. HINSHAW, Rochester.

Correlation of the Use of Antibiotic and Chemotherapeutic Agents with General Principles of Surgery.

CHAMP LYONS, New Orleans.

OPHTHALMOLOGY

Tuesday

Orbital Reconstruction Including Prosthesis

Acrylic Prosthesis. A. D. RUEDEMANN, Cleveland.

Basket Implant. NORMAN L. CUTLER, Wilmington.

Orbital Measurements.

Reconstruction of Upper Lid and Orbital Floor Defects. Major ARTHUR E. SHERMAN, Springfield Missouri.

Thursday

Surgical Applied Anatomy in Eye Surgery. MEYER WIENER, Colorado.

Visual Disturbances Associated with Head Injuries. JOHN MCGAHEY, Fort Madison.

OTORHINOLARYNGOLOGY

Tuesday

Treatment of Deafness

The Suppurating Ear.

The Fenestration Operation. GEORGE E. SHAMBAUGH, JR., Chicago

Use of Radium for Conductive Deafness. JOHN E. BORDLEY, Baltimore.

Thursday

Surgery of the Nasal Accessory Sinuses

Indications for Surgery in the Light of the Use of Antibiotics.

Intranasal Surgery. JOHN J. SIEA, Memphis.

External Operations.

SYMPOSIUM ON PLASTIC SURGERY OF THE HEAD AND NECK

Wednesday 8 p.m.

Cancellous Bone Grafts to the Jaw.

Repair of Nasal Defects with Free Composite Grafts of Skin and Cartilage from the Ear. JAMES B. BROWN, St. Louis.

Studies in the Anatomy and the Repair of Cleft Palate.

Preservation of Function Following Resections of Jaw Tumors.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday, 1:30-3:00 p.m.

Rehabilitation of the Surgical Patient and Early Ambulation. Leader, HOWARD RUSK, New York.

Monday, 3:30-5:00 p.m.

The Treatment of Cancer of the Large Bowel. Leader, FREDERICK A. COLLIER, Ann Arbor.

Tuesday, 1:30-3:00 p.m.

Thiouracil in Thyroid Disease. Leader, FRANK LAHEY, Boston.

Tuesday, 3:30-5:00 p.m.

Recent Trends in the Management of Carcinoma of the Cervix. Leader, JOE VINCENT MEIGS, Boston.

Wednesday, 1:30-3:00 p.m.

Anesthesia. Leader, HENRY K. BEECHER, Boston.

Wednesday, 3:30-5:00 p.m.

Protein Metabolism in the Surgical Patient. Leader, ROBERT ELMAN, St. Louis.

Thursday, 3:30-5:00 p.m.

Spinal Cord Injuries. Leader, HOWARD C. NAFFZIGER, San Francisco.

Friday, 1:30-3:00 p.m.

Surgery of the Stomach. Leader, ROSCOE R. GRAHAM, Toronto.

Friday, 3:30-5:00 p.m.

Surgery of the Vascular System. Leader, DANIEL C. ELKIN, Atlanta, Georgia.

SURGICAL SPECIALTIES

Friday 2:00-5:00

Orthopedic Surgery Panel. (Subject to be announced.) Leader, CARL E. BADGLEY, Ann Arbor.

Urology Panel. (Subject to be announced.) Leader, HERMAN L. KRETSCHMER, Chicago.

Plastic Surgery Panel. (Subject to be announced.) Leader, ROBERT H. IVY, Philadelphia.

Neurological Surgery Panel. (Subject to be announced.) Leader, FRANCIS C. GRANT, Philadelphia.

Obstetrics Panel. (Subject to be announced.) Leader, FREDERICK C. IRVING, Boston.

Thoracic Surgery Panel. (Subject to be announced.) Leader, RICHARD H. SWEET, Boston.

OPHTHALMOLOGY

Panel discussions in the field of Ophthalmology are planned for Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock, on the following subjects: Retinal Detachment; Glaucoma; Keratoplasty.

OTORHINOLARYNGOLOGY

Panel discussions on subjects in the field of Otorhinolaryngology are planned for Tuesday, Wednesday and Thursday mornings at 11:00 o'clock on the following subjects, respectively: The Treatment of Ménière's Disease; Osteomyelitis of the Skull; Rehabilitation of War Deafness.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

AT 2:00 o'clock on Tuesday afternoon there will be held a symposium on Fractures and Other Traumas under the direction of Robert H. Kennedy of New York. This symposium will be devoted to a number of brief presentations by specialists in various fields concerning new or improved methods adopted during the war which are applicable to injury in civilian surgery. The aim is to give a rapid survey of worthwhile gains made during the war which may prove of lasting value in the field of trauma.

Among the fifteen or twenty short papers which are planned are the following:

Bone Grafts. GEORGE K. CARPENTER, Nashville.
Spinal Cord Injuries. DAVID H. POER, Atlanta.

Injuries to the Rectum. EDMUND J. CROCE, Worcester.

Transportation of Fractures. WILLIAM J. STEWART, Columbia.

Replacement of Skin Defects. JAMES B. BROWN, St. Louis.

Fractures of the Carpal Scaphoid. MATTHEW CLEVELAND, New York.

Amputations. RUFUS H. ALDREDGE, New Orleans.

Training of Amputees. HENRY H. KESSLER, Newark.

Rehabilitation. Col. A. WILLIAM REGGIO, Washington.

Compound Fractures Treated with Penicillin and Delayed Primary Closure. OSCAR P. HAMPTON, Jr., St. Louis.

SYMPOSIUM ON CANCER

A symposium on cancer is planned for Wednesday afternoon. The Cancer Committee of the College has done outstanding work in furthering the development of cancer clinics in hospitals and providing for the registration of cured cases of malignant disease in the cancer archives. The chairman of this com-

mittee will give a brief review of these activities of the College in opening the symposium.

Other subjects of practical interest are under consideration for inclusion in the program, which is being planned to interest surgeons, pathologists, and radiologists.

COLLECTIVE REVIEW

SPLENECTOMY, WITH SPECIAL REFERENCE TO ITS HISTORICAL BACKGROUND

The Indications and Rationale, and a Comparison of Reported Mortality

H. L. PUGH, Captain, (M.C.), U.S.N.

AS IS nearly always true of any situation wherein a mystery exists, a special interest attaches to that situation because of the mystery. This has for long been the case with reference to the spleen and in this instance the mystery is all the more fascinating because of the multiplicity of its elements which include (1) the functions of the spleen; (2) the role played by the spleen as a cause of certain systemic diseases; (3) the effect upon the spleen of diseases not primarily splenic; and (4), finally, the mystery as to the rationale of surgery in certain instances—and it may as well be said in the beginning that practically the only surgery applicable to the spleen is splenectomy. However, regardless of whatever the degree of appeal a discussion of the spleen and splenectomy may hold because of the mystery which persists in surrounding that organ, a justification for the publication of this article is sought upon entirely independent grounds, namely: (a) to present a brief review of the literature and compare the concepts voiced during the last half of the last century with those prevalent at the beginning and, finally, with those of the middle of the present century; (b) to refresh the mind of the surgeon with respect to knowledge he should possess relative to the alleged functions of the

spleen, the indications for splenectomy, and the results which may be contemplated, in order that he may render a comprehensive expression of opinion and make well advised recommendations when called in consultation; (c) to point out certain operative technicalities deemed worthy of consideration; (d) to consider the mortality rate from splenectomy, past and present; and (e) to report a series of 15 splenectomies.

HISTORICAL

There appears to be considerable confusion in the literature as to when the first successful splenectomy was performed. Legend has it that the marathon runners in the last century B. C. used to have their spleens removed "to improve their wind." The "Talmud" (200-600 A. D.), according to Macht (44), contains references which indicate that not only were runners deprived of their spleen in order to increase their efficiency, but that spleens were also removed from horses as a means of augmenting their speed. Similar reference is found in the "Natural History of Pbnv," from 23 to 79 A. D. and in the Arabic literature, according to this author. Macht (45), moreover, in a series of experiments on rats, was able to demonstrate an apparent improvement in the running speed of splenectomized animals. Krumbhaar (46) in his edition of Castiglioni's "History of Medicine" (page 551) makes reference to an experimental splenectomy performed by Guiseppe Zambaccari of Florence in the 17th

From the Surgical Service U.S. Naval Hospital, San Diego, California, now Medical Officer in Command, U.S. Naval Medical School, National Naval Medical Center, Bethesda, Md.

The opinions or assertions contained herein are those of the writer. They are not to be construed as official or reflecting the views of the Navy Department or the Naval Service at large.

century, and on page 720 of the same book, reference is made to Gustav Simon's (1824-1876) having (in 1857) reintroduced the "forgotten" operation of splenectomy. Again from page 840, the following sentence is copied: "Splenectomy, which began centuries earlier with Zaccarelli (1549) and Zambaccari (1680), was revived in the modern period by Kuechler in 1855 and Spencer Wells in 1866." However, the first published operation on the spleen is said, by Alessandri, to have been that by Viard in the 16th century. The vessels were ligated and the spleen was left in.

In 1856 Adelmann of Berlin collated 15 splenectomies. Beyond the statement that the operation was done for various diseases and injuries, no specific indication is given in the reference by Russell. In 1880, Russell, in a treatise upon the management of splenic injuries associated with exposure upon the indication and justification for operative intervention in case of trauma to the spleen, but no forthright mention was made of a single splenectomy having been done in his series of 39 cases, 28 of which terminated fatally and, as a matter of fact, the diagnosis in the remainder was apparently only presumptive.

Fowler states that the first splenectomy for cyst was performed in 1880 by the French surgeon Pean. Heineck credits the first splenectomy to Roddick in 1885. The spleen in this instance is said to have been removed through a small opening in the lumbar region. The reference fails to indicate for what condition this operation was performed. If for a condition other than rupture, it need not necessarily be in conflict with the statement by Bier *et al.* that the first splenectomy for rupture was performed in 1892. Albeit, it does seem unlikely that the series of 37 splenectomies for ruptured spleen reported in 1900 by Bessel-Hagen (13) should all have been done after 1892.

In any event, that the spleen is not essential to the human economy has been known for a long time. Bardeleben, over 100 years ago, demonstrated conclusively that its removal from healthy animals could be accomplished without deleterious effect. According to the answers to examination questions for admission to the Medical Corps of the Navy which the author has had occasion to read, there seems to be a popular belief in some quarters that certain animals, notably the zebra and giraffe, may be minus a spleen by reason of failure of development. Owen in his work on the anatomy of the vertebrates described the spleen in all manner of animals from the ornithorhynchus to the giraffe and elephant and makes no mention of its being absent in any species of animal.

The list of conditions for which splenectomy has been advocated has changed to an appreciable degree with the passage of time. Some of the conditions which were formerly regarded as indications have been dropped from the list, while others have been added as our knowledge with respect to the physiology of the spleen and its relationship to certain diseases has increased. It is now well recognized that in the light of modern surgery, splenectomy is imperative under certain conditions, distinctly indicated in others, and probably indicated in others. It must be admitted, nevertheless, that most of our modern knowledge with respect to the spleen and splenectomy has been arrived at by accident, or the it

In a very comprehensive paper on splenectomy by George Ben Johnston, published in 1908, 15 indications for splenectomy were listed. Six of these indications, however, are contained in a tabulation of idiopathic and malarial hypertrophy without or with complications such as ectopy and/or twisted pedicle. In 1928 Edwin Beer listed which splenectomy as one of the conditions for which splenectomy had been done but stated that the results had been so unsatisfactory as to lead to the abandonment of this procedure. In a series of 153 splenectomies for pernicious anemia collected by Krumbhaar (41) only 2 patients were alive after 2 years, and both of whom still suffered from pernicious anemia.

It is interesting to note that one quarter of a century ago Beer's concepts relative to the indications for splenectomy were practically the same as those expressed by the present day commentators on the subject. Devine, in his textbook, Whipple (68) reported 1,457 patients with splenic lesions seen over an 18 year period by the combined splenic clinic of the Columbia Medical Center. These cases were separated into 20 categories, in only a few of which, however, was splenectomy indicated, as only 174 splenectomies were done in the whole reported series. In 1941, Hayden classified the indications for splenectomy, listing the several conditions in order of their urgency or advisability, and gave lastly a list of conditions for which splenectomy is sometimes done but is contraindicated. In 1943, Pernikis published an excellent discussion on the three principal medical or hematopoietic dyscrasias for which splenectomy is indicated.

In the military service the most common indication for splenectomy is rupture of the spleen. This was true particularly during the war and was incident not only to combat casualties but to the

Fig. 1. A. Delayed rupture of spleen. Trauma, blow from thrown baseball 3 weeks previously. B. Hodgkin's disease. This case had been erroneously diagnosed preoperatively as Banti's disease.

increased tempo of activity in general, and to vigorous physical activity in camps, training stations, and Navy Yards. In the Navy 69 splenectomies for noncombat rupture were reported during the years from 1942 to 1944, inclusive. Another factor which may be alleged to have contributed to the rupture of spleens among the Naval and Marine Corps personnel during the early part of the late war was that of malaria. Malarial spleens may rupture spontaneously although this is a rare occurrence (Kellner *et al.*). In any event, a malarial spleen is more prone to rupture when subjected to violence than a normal spleen.

FUNCTIONS

Numerous functions have been ascribed to the spleen, some fanciful and some factual. However, since it is with respect to its physiology that some of the interesting elements of its enigma prevail, it would appear desirable to review at this point the several functions which have at one time or another been claimed for the spleen. Some writers more or less dogmatically enumerate the functions of the spleen, while others express considerable reservation in their estimate of its physiology. Actually there appears to be little more irrefutable proof of the functions of the spleen today than existed 50 years ago.

The spleen is generally accepted to be a part of the reticuloendothelial system, of which the liver, the medullary tissue of the bone, the lymphatic glands, and the cortex of the adrenals are the other constituent additional organs or tissues. This view is based largely upon the existence of a type of cell common to the several named structures. It is believed that following splenectomy the spleen's function is taken over by the remaining organs of the reticuloendothelial system. From Hippocrates, who admitted a lack of knowledge about the spleen, and Galen, who hazarded the guess that it had something to do with the purification of the blood, down to the present, the veil of mystery has only partially been lifted by our modern advances in physiology. Nevertheless, there is one anatomical feature which above all other considerations bespeaks the fact that the spleen performs an extremely energetic function, whether that function be essential or nonessential, and that is its vascular system, both afferent and efferent, of inordinate capacity. Aschoff and Landau point out that the well oxygenated arterial blood delivered to the spleen indicates that some substance is being oxidized but that deoxygenation of the blood in itself is not believed to be a splenic function. It is concluded that the oxygen is used in the

Fig 2 Solitary retention cyst of the spleen.

destruction of deleterious substances or in the elaboration of some complex substance such as the hemoglobin protein molecule. Of the functions which have been more commonly ascribed to the spleen, the following may be reviewed:

1. That of a hematopoietic organ in prenatal life and perhaps during infancy and a "burial ground" for disintegrated and worn out red blood corpuscles, beginning probably in childhood and continuing on through adult life. The destruction of red corpuscles results in the liberation of hemoglobin. This is said by some to be conveyed through the splenic vein to the liver where it is converted into bilirubin. Pernokis points out that many investigators have been unable to demonstrate any difference between the intermediary or antecedent elements of bilirubin in the splenic artery and vein and believes with them that the liberated hemoglobin is transformed into bilirubin within the spleen itself.

2. It has for long been taught that the spleen manufactures lymphocytes and monocytes in the lymphoid tissue of its malpighian corpuscles in conjunction with the lymph glands of the body in adult life, and that in the case of certain dyscrasias such as splenomyelogenous leucemia there is an effort on the part of the spleen to revert to its fetal role. Hypertrophy of the organ and the liberation into the circulation of numerous abnormal cells is a natural consequence. Whether these abnormal cells are actually formed in the spleen or whether the influence of a deranged spleen on the bone marrow is responsible for the formation of abnormal cells by the marrow is debatable.

3. The absorption, assimilation, and storage of iron liberated from the decomposition of red blood cells is a role ascribed to the spleen. This iron is combined with hemoglobin and represents from 92 to 98 per cent of the total iron, according to Williams and Wilkins. The remainder of the iron in the body is liver iron and is derived from the feeding and ingestion of iron. Normal blood contains from 45 to 55 milligrams per cent of iron. The total quantity present in the average adult human is about 4 grams. If iron is metabolized by the spleen from hemoglobin obtained or liberated from disintegrating red blood cells, the process must be complete within the spleen since, as it has been observed, there is no difference between the hemoglobin content of the splenic artery and that of the splenic vein.

4. The spleen is said to act as a kind of vascular reservoir for the portal and splanchnic systems. In this capacity it has the property of discharging an additional quantity of blood as needed. Barcroft and Stephens believe that the splenic reservoir is capable of containing about one-fifth of the circulating blood. That the spleen contains a considerable amount of nonstriated muscle tissue, and that it possesses the quality of executing rhythmic contractions comparable to those of the gastrointestinal tract and the uterus, are factors which are consistent with its alleged function as a reservoir. The theory has been advanced that the pain experienced in the left flank upon exercise may be due to the contraction of the spleen in its effort to force pure blood into the general circulation. Since this type of pain is common in long distance runners, it is thought

Fig. 3. Schematic illustration of the portal circulation, and its tributaries and connections which constitute the setup for the development of varices on the abdominal wall, esophagus, and rectum as a consequence of obstruction and hypertension in this system.

that it may account for the tradition that the ancients removed the spleen of runners in preparation for the marathon races.

5. To assign to the spleen the function of a blood filter is to credit it with one of its oldest alleged functions. It is in this capacity as a filter that it removes the spheroidal cells which are characteristic of hemolytic jaundice and produces a hypertrophy of the organ and a paucity of circulating red blood cells. When the spleen is removed, these spheroidal cells are free to continue in the circulation and to perform their function just as if they were normal red blood corpuscles.

6. The belief formerly voiced by a number of writers, that blood platelets were produced by the spleen, is no longer tenable in the light of more recent knowledge of hematology. The modern teaching is that blood platelets are manufactured by the red bone marrow because they are the direct descendants of the megakaryocyte which is in turn a descendant of the megakaryoblast, a marrow cell. In thrombocytopenic purpura, the red bone marrow is believed to be inhibited in the manufacture of platelets by a perverted splenic hormonal influence.

7. That the spleen shares in the nitrogenous metabolism is based more on fancy than concrete

Fig. 4. Artist's drawing showing anterior view of splenic pedicle with major vessels and ligamentous attachments of the spleen.

evidence. The proponents of this theory fail to define in what respect and to what extent this is true.

8. The claim has been made that the spleen is a storehouse for various antibodies and is, therefore, instrumental in resisting infection. This is an attractive theory and, while not proved, it is interesting to note that in a series of splenectomized rats injected with pest culture 87 per cent died while only 22 per cent of the controls died (Beer). There seems to be appreciable evidence that bacterial toxins and bacteria introduced into the venous system may be taken up and fixed by the spleen. Granted that malignant metastases to the spleen are rare, there is no very substantial evidence that the spleen possesses an inherent resistance to neoplastic growth.

9. Moynihan (50) accorded the spleen membership in the sympathicoendocrine system.

10. That the spleen elaborates ferments or a hormone which influences the function of the bone marrow appears probable in view of the beneficial results which follow splenectomy in certain cases of Banti's disease and in thrombocytopenic purpura.

PATHOLOGY

It would appear appropriate, next, to review the pathological conditions for which splenectomy

is indicated. W. J. Mayo observed that the spleen was much more important pathologically than physiologically. The conditions in which splenectomy is followed by the most gratifying response may be listed as follows:

1. Local disease or injury (neoplasm, cysts, abscess, and rupture)
2. Banti's disease
3. Congenital hemolytic icterus
4. Essential thrombocytopenia

Although splenectomy may be done, and done to advantage, in certain other diseases, such as (a) sickle cell anemia (Hayden), (b) primary splenic neutropenia (Wiseman and Doan), (c) primary splenic panhematopenia (Doan), (d) tuberculosis of the spleen—if there is evidence of what has been referred to by some authors as a "hemming" action on the bone marrow, and (e) certain cases of Gaucher's disease or lipoid reticulo endotheliosis (Hoffman and Makler), certainly the overwhelming majority of indicated splenectomies are done for the conditions listed under the four headings given previously.

Neoplasm. Malignancies of the spleen, either primary or secondary, are rare, lymphosarcoma and Hodgkin's disease are listed as the more likely malignant conditions to attack the spleen. In 2 of the splenectomies reported in the present series, the latter condition was established as the diag-

Fig. 5. Artist's drawing showing posterior view of splenic pedicle with ligamentous attachments and anatomic relationship to tail of pancreas and left kidney.

nosis upon histopathological examination of the removed spleen. The spleen of one of these patients is represented by Figure 1B. Primary carcinoma of the spleen appears never to have been established in any case which would bear investigation. Secondary carcinoma is uniformly referred to as being extremely rare (Moynihan (51) and Boyd). When it is considered that lymphatic tissue is so abundantly present in the spleen and this tissue must be constantly exposed to carcinomatous cells which are brought in by the blood stream, it is amazing that it is not as common a site for malignant metastases as is the liver, at least. Whether or not its resistance to malignant growth is due to some immune quality inherently present in the spleen is a matter upon which there has been considerable conjecture but no very convincing conclusions.

Cysts. The most common type of cyst of the spleen is the hydatid cyst, but this is found only in countries where hydatid, or echinococcal, disease prevails. True retention cysts of the spleen are very rare in occurrence (only 4 were found in a series of 800 splenectomies at the Mayo Clinic) and are more rarely diagnosed preoperatively. They usually contain serous or serosanguinous fluid. Such a cyst (Fig. 2) constituted the indication for one of the splenectomies herewith

reported and the diagnosis was made preoperatively. Fowler gleaned from the literature up to January, 1939, reports of 137 nonparasitic cysts of the spleen. Of this number 29 per cent were of the large variety with serous content. In 1942, Maclure and Altemeier reported 148 cysts of the spleen as having appeared in the literature up to 1941.

The pathogenesis of splenic cysts is not well understood. Fowler's classification of cysts of the spleen into primary or true, and secondary or false is reasonable in its concept and affords a good working basis. Pepere believes that all serous cysts of the spleen originate from cellular inclusions or inverted vestiges of the serous endothelia.

Acute splenic tumor is an accompaniment of many acute infectious diseases but a well defined abscess of the spleen is rare. When present, incision and drainage are far preferable to splenectomy.

Trauma. Rupture of the spleen, whether immediate or delayed, is a leading contender for the right of way as a surgical emergency. The treatment for this condition, it may again be bluntly stated, is splenectomy. Several special diagnostic criteria for ruptured spleen have been enunciated in the literature. Pain in the left shoulder (omalgia), sometimes described as Kehr's

Fig. 6. Artist's drawing indicating anatomic relationships and illustrating the manner in which peritoneal reflections enter into the formation of splenic ligaments. For the sake of artistic clarity, certain of these ligaments have been made to appear much more distinctly defined than they actually are found. The splenicocolic and splenicorenal ligaments are frequently so diaphanous in character as to be scarcely recognizable as ligaments at all.

sign (Armitage), the signs of Pitts and Ballance, or persistent dullness on the left side with shifting dullness on the right side on percussion are mentioned by Heineck as being pathognomonic. A rupture of the spleen should be thought of in all cases in which there is evidence or a history of an intra-abdominal injury. Mazel is quoted by Angle and Kassel as having reported in a review of the literature, that involvement of the spleen was found in 30 per cent of all abdominal injuries. This figure is thought to be high. In any event, the usual signs of an acute surgical belly plus the

classical signs of internal hemorrhage with or without a history of injury should lead the surgeon to consider rupture of the spleen as a very definite possibility. Evidence of shock may be pronounced or surprisingly slight. The difficult cases from a diagnostic standpoint are those in which a delayed rupture constitutes the disability. Santini *et al.* in discussing delayed splenic rupture suggest that three stages may be considered: (1) the original injury, (2) the latent period, and (3) the period of acute intraperitoneal hemorrhage. The ideal thing would be to make the diagnosis and perform

This fascinating, controversial, and mysterious disorder, thought by many to be a syndrome rather than a disease *sui generis*, was first described by Banti in 1882. Fundamentally it is characterized by an anemia associated with splenic enlargement, cirrhosis of the liver, and ascites. The white blood count in Banti's disease is characteristically low—between 2000 and 3000.

As early as 1907 Herrick expressed his views relative to the cause of increased portal pressure in portal cirrhosis. However, it was not until relatively late years that the existence of back pressure in the splenic vein has come to receive considerable emphasis as a factor in Banti's disease. Whether this hypertension in the splenic vein is a cause or an effect is a moot question in the minds of some. Thompson, Whipple *et al.* (64) have contributed appreciably to the expression of

It was Thompson's view originally that cirrhosis of the liver was only one obstructive cause and that if splenectomy was instituted before it developed, the subsequent development of splenic anemia would be prevented. Why this should be true, if it is, is still not readily understood. In any event the theory has been advanced and considerable substantiating evidence offered by these authors, to the effect that pressure in the portal system from any cause such as schistosomiasis, neoplasm, thrombosis of the portal vein, or cirrhosis of the liver, which would tend to increase the back pressure, can produce the clinical picture of Banti's disease. It is upon this predication that the contention for referring to the symptom complex as a syndrome rather than a disease is based. A review of cases in which the response to splenectomy is generally agreed.

The anemia in Banti's disease is believed by certain individuals to be due to a pressor effect of the spleen on the bone marrow probably through a hormonal action or some internal secretion.

Naegeli (52, 53) was a leading exponent of this view. The removal of the spleen in these blood dyscrasias relieves the bone marrow of the influence of the spleen and permits the release of the various elements manufactured by it into the general circulation. It is interesting and baffling to note that in none of the blood dyscrasias previously listed and benefited by splenectomy was there histopathological evidence of what the mischief making mechanism in the spleen may be.

Certain findings are of ominous prognostic import and are regarded by some as contraindications to operation. High on this list of unfavorable indications are ascites and hemorrhage from the esophageal or gastric varices. According to Hanrahan, the existence of a microcytic or pseudomicrocytic anemia indicates a pathological change in the liver and implies an impending exodus regardless of whether or not surgery is done. Statistics indicate that while splenectomy in Banti's disease is frequently not attended by improvement of the patient's condition, by and large, it offers the patient more than any other therapeutic agent or measure yet introduced. It is "the one proved life saver in Banti's disease" (Babcock).

In advanced cases of Banti's disease it is likely that the spleen will have become so adherent as to make its removal virtually impossible without a grave risk of precipitating a fatality and, moreover, it is contended by some surgeons that the tendency toward hemorrhage from varices might be increased by splenectomy if a collateral circulation or bypass for venous blood has become established through the spleen. To understand the mechanics requisite to satisfy this situation, it is necessary to visualize that collaterals have developed in the dense adhesions between the spleen and the diaphragm, through which the venous return could be shunted into the general circulation (a circumstance which would render the removal of the spleen too hazardous and too dangerous). Also, the blood leaving the spleen by way of the vasa brevia and then entering the left gastric vein is, in its turn, shunted into the esophageal veins which enter the left gastric vein, and is ultimately backed through the esophageal veins into the azygous system; it then enters the vena cava and by-passes the liver. This backing-up process may go on so far as to force a reopening of the venous tributaries which have lain more or less dormant since fetal life, and to dilate others whose function has been of a limited nature. Thus the umbilical veins and veins of the round ligament may become enlarged and the phenomenon characterized by varicosities on the anterior

abdominal wall, sometimes referred to as Couvelhier-Baumgarten's syndrome, or a caput medusa, is produced. It is a notable fact that bematemesia which develops or increases following splenectomy is of grave prognostic significance.

As a refresher on the anatomical relationship of the portal and general circulations and as an aid to a better understanding of the mechanics involved in the development of varices of the esophagus and abdominal wall as a consequence of portal obstruction, Figure 3 has been prepared.

Congenital hemolytic icterus. The next of the so-called medical triad, in order of frequency of occurrence as well as in time elapsed since it first received recognition as a clinical entity, is congenital hemolytic icterus or spherocytic icterus. Having been first discovered by Minkowski in 1900 and Chauffard in 1907, it is sometimes referred to as acholuric familial jaundice of the Chauffard-Minkowski type.

This disease is usually thought to be congenital, but it may be acquired. If acquired, it is known as the Hayem-Widal type (Babcock). Thompson (65), in 1939, reported 43 cases of hemolytic jaundice seen over an 18 year period at the combined splenic clinic of the Columbia Medical Center. Splenectomy was performed upon 30 patients of this series. In 1945, Pemberton and Kiernan reported 233 splenectomies at the Mayo Clinic for hemolytic jaundice between the years 1904 and 1944. Also, in 1945, James and Evans reviewed 15 cases of acquired hemolytic jaundice with onset after the patients were 50 years of age and found that 5 showed improvement after splenectomy. Of these patients, 3 were past 70 years of age.

The diagnosis of this disease is based upon recurring attacks of jaundice of varying degree without increase of bile in the urine and without evidence of diminution of bile in the stools. The jaundice is due simply to an inordinate destruction of the red blood corpuscles. There is characteristically a pronounced anemia which is frequently severe. The blood corpuscles, as seen on a smear, tend to be microcytic and spheroidal rather than discoid in shape. Reticulocytes and nucleated red cells are common in the peripheral circulation. Equally as important as any single finding in this disease is an increase in the fragility of the erythrocytes. It is interesting to note that while neither the degree of fragility nor the presence of spherocytes in the peripheral circulation is apparently affected by splenectomy, the patient's improvement may be phenomenal.

Furthermore, it is interesting to note that according to Kirkegaard and Kirkegaard, the duration of life of the erythrocytes in patients

with hemolytic jaundice is from one-tenth to one-twentieth of the duration of life of normal erythrocytes. These authors also point out that in acquired hemolytic jaundice, the erythrocyte and reticulocyte counts and the hemoglobin percentage may be expected to reach their original value from 4 to 6 days after a transfusion. Thus, it is seen that normal erythrocytes live only from one-fifth to one-tenth their normal lifetime when transfused to patients with hemolytic jaundice. The role of the spleen in the pathogenesis of this disease is reckoned by Kirkegaard and Kirkegaard to be a dominant one.

Biopsy of the bone marrow in this condition is of diagnostic assistance in that spherocytes are found in the bone marrow and the erythroid precursors preponderate over the myeloid to an inordinate degree.

The mechanics of why the spleen enlarges and why the patient becomes anemic with this disease seem fairly readily explainable on the theory that because of their shape, spherocytes will not pass the interstices or the filter structure of the spleen and are therefore filtered out, which causes at the same time a paucity of circulating cells and splenomegaly. This, however, as Thompson (65) points out, still leaves unanswered, three questions: (1) What is the genetic origin of spherocytes? (2) Why the jaundice? Why the associated destruction of the red blood cells? (If the answer is in increased fragility, the question of why is yet equally in order.) and (3) What is the role played by the spleen of an individual affected with spherocytic jaundice that a normal spleen would not play. Granted that the anemia is relieved by removing the trap or filter, the question as to why the fragility remains unchanged in an appreciable number of cases is still unanswered.

A most interesting and surprisingly common concomitant finding in cases of hemolytic icterus is the presence of gall stones. The incidence in Pemberton and Kiernan's series of 233 cases reported from the Mayo Clinic was 71.2 per cent. That gall stones form as a result of the constant excess of bile pigment from the protracted hemolysis of the red blood corpuscles seems logical. In any event, the symptoms of gall stones sometimes predominate and lead to surgical intervention for cholelithiasis.

While "familial" is a qualification commonly applied to this disease, Thompson (65) does not believe that a history of familial occurrence is of differential diagnostic importance.

Essential thrombocytopenia. Lastly we come to consider the junior member of the trinity of spleen influenced blood dyscrasias—purpura hemor-

rhagica, or thrombocytopenic purpura. Splenectomy for this condition was first introduced by Kaznelson, a student in Prague in 1916. There are two more or less definite forms, the acute and chronic. The results commonly obtainable from splenectomy for this condition are dramatically brilliant. In the acute form, there is justification for deliberating only long enough to determine whether medical measures will be effective. The mortality rate from splenectomy in the acute form or during an acute exacerbation is much higher than when the operation is performed during a quiescent phase. However, it is dangerous to wait and certainly there is no more certain means of bringing about a cessation of purpuric hemorrhage than by splenectomy.

In chronic thrombocytopenic purpura, the results from splenectomy are uniformly more gratifying than from any other condition in which splenectomy is indicated, save for ruptured spleen. The incidence of the disease is about on a par with spherocytic hemolytic anemia. Pemberton and Kiernan reported 153 cases over a 21 (1923-1940) year period at the Mayo Clinic, and Elliott, of Columbia Medical Center, New York, reported 42 cases seen over a period of 10 years, upon 22 of which splenectomy was done. The diagnosis of thrombocytopenic purpura hinges chiefly upon the finding of a low platelet count in an anemic patient with purpuric manifestation. There is also a long bleeding time with a normal clotting time. The clot is slow to retract. There is an absence of premature cells and the regenerative propensities of the blood forming mechanism are apparently normal. The spleen is not characteristically enlarged and, as is pointed out by Hayden, it is the only condition except ruptured spleen in which splenomegaly is not part of the indication for splenectomy. Sternal puncture is important in that, by this measure, aleucemic leucemia and aplastic anemia which are extremely difficult to differentiate from hemorrhagic purpura can be ruled out.

COMMENTS UPON OPERATIVE TECHNIQUE

The operative technique in splenectomy has been fairly well standardized for a long time. Aside from a few suggestions which the author believes may be worthy of mentioning, the reader will not be hurdened with a detailed description of the surgical removal of the spleen. It has often been said by experienced surgeons that a splenectomy may be one of the simplest of operations, or it may be impossible, and that the competency of the surgeon in surgery of the spleen may be gauged chiefly by his ability to differentiate be-

tween an operable and an inoperable spleen. The one important point to remember is that, unlike certain other operations, the operation of removing the spleen is, in most instances, not one which will lend itself to compromise. Once the surgeon has decided to remove the spleen—and in case of rupture there is virtually no alternative—he should set about it in a bold and methodical manner. Troublesome adhesions are more apt to be present in Banti's disease than in any other condition for which splenectomy is indicated. When these adhesions are dense and extensive the wiser policy is to regard the spleen as inoperable, because after the pathological process has advanced to a stage where the adhesions interfere seriously with removal of the organ the clinical course of the disease will not (unless adversely) be affected by its removal. The manner in which the effect of splenectomy may prove detrimental has been alluded to in the discussion of Banti's disease.

In the anatomy books there are described several ligaments, chief among which are the phrenicosplenic ligament and the gastrosplenic ligament, whose function it is to hold the spleen in position. These ligaments, in reality amount to nothing more or less than peritoneal reflections (Figures 4, 5, and 6). The strongest is the phrenicosplenic ligament which merges with the gastrosplenic ligament. When the ligamentous attachments of the spleen are redundant and permit preternatural mobility, the spleen may become dislodged from its fossa and descend even into the pelvis. Hence the term "wandering spleen."

According to the writings of earlier surgeons, a "wandering spleen," particularly when it became twisted upon its pedicle, was a more or less common indication for splenectomy. Indeed the prominence assigned to this condition as an indication for splenectomy by earlier and more modern authors prompts this author to stray afield in order to comment briefly upon it. It is amazing to note that among the series of 708 splenectomies reported by Johnston in 1908, which number contained Bessel-Hagen's (14) series of 353, ectopy associated with either idiopathic or malarial hypertrophy was listed as the indication for splenectomy in 139 cases, and in 30 of these the pedicle was twisted. In the report by Whipple (68) of 1,437 cases seen at the combined splenic clinic of Columbia Medical Center over a 10 year period, 20 conditions in which the spleen played a dominant role were listed but ectopy or "wandering" spleen was not mentioned. In 646 splenectomies performed at the Mayo Clinic up to 1934 and reported by Mayo and Giffin, ectopy

constituted the indication only twice. Subsequent to 1934, in the 357 additional splenectomies (making a total of 1,003 by January 1, 1945) at the Mayo Clinic (Giffin), ectopy was not encountered in a single instance. This writer has never seen a spleen so mobile and displaced to such degree as to qualify it for the designation of "wandering" spleen. Of course, in certain cases of general viceroposis, the spleen may be found, along with the stomach, in the lower part of the abdomen.

In any event, the several ligaments may, in most instances (Banti's disease is a notable exception), be separated from the spleen without difficulty by passing the hand around the organ and separating it from its ligamentous attachments. If extraordinary resistance is met by the hand, the ligaments may be readily divided by the use of scissors. A note of warning should be sounded apropos the use of scissors on the gastrosplenic ligament since it is entirely possible for one to enter the stomach inadvertently without being aware of it. The separation of the spleen from its ligamentous attachments always seems more readily accomplished with a ruptured spleen.

This is fortunate because expedition in delivery is usually more vitally essential in this condition. Nevertheless, whatever may be the reason for splenectomy, expeditious delivery of the spleen from its fossa and into the abdominal wound is highly desirable. Many operators speak of short pedicles and difficult delivery of the spleen. If the incision is high and long enough, this writer believes that no spleen should be difficult to deliver because of the length of its pedicle. The important circumstance provided by the delivery of the spleen is the exposure of the pedicle, which renders accessible the major vessels (Fig. 4). Ideally, it is contended that the splenic artery should be identified and ligated first, to be followed by gentle massage of the spleen or even the introduction of 2 cubic centimeters of pituitrin into its pulp by means of a syringe and needle, immediately prior to ligation of the splenic vein. The reason is that by an observance of this technique, a definitely appreciable amount of blood (in large spleens, 500 c.c. or more) can be conserved. An aneurysm needle seems to have been banded down as the classical ligature carrier for passing the ligature around the splenic vessels. Actually, few surgeons try to identify and ligate the large vessels independently but, instead, they seize the whole pedicle by means of several large and reliable clamps and apply and securely tie "stick ties" upon removal of the clamps. Whether absorbable or nonabsorbable ligature material is

used seems to make no difference. When the spleen is first delivered into the wound, its fossa, or that area bounded by the diaphragm above, and the stomach (mesially) should be packed with several large, hot, wet laparotomy sponges which are left in place until ligation of the pedicle has been completed, when they are removed and the abdomen is closed.

The only hazard of any consequence in removing a ruptured or nonadherent spleen is that of hemorrhage from the pedicle due to tearing of the veins, which are sometimes extremely frail in structure by the ligatures. While one of the accidents which seasoned surgeons warn against is that of tying the tail of the pancreas in the ligatures placed upon the splenic vessels, the writer has deliberately included a small portion of the tail of this organ in the vessel ligatures in several instances to safeguard against their cutting through, and has witnessed no deleterious effect from such procedure. The only other score upon which serious trouble may arise in connection with splenectomy is, as has been mentioned, the accidental entrance of the stomach. This occurred in 1 of the cases reported in the accompanying series but was promptly recognized, and following closure of the rent, which was 2 inches in length, no untoward development ensued.

Two postoperative complications alleged by numerous observers to follow splenectomy are phlebitis of the splenic and portal veins, and the development of thrombi. The latter is said to be particularly likely to occur following splenectomy for Banti's disease and is explained on the basis of an increase in the blood platelet count due to the removal of the spleen combined with retardation of the blood flow through the portal vein incident to the inherently present portal hypertension. Such may have been the explanation for the sudden death of a patient 11 days following splenectomy for Banti's disease, which was done by the author on a native in Guam 10 years ago.

While thrombosis of the portal and splenic veins may not be uncommon following splenectomy for the several blood dyscrasias in which the operation is indicated, or for an organic disease of the spleen, it has rarely, although occasionally, been reported in association with splenectomy for a traumatic spleen (Weissenborn and Gius *et al.*). The symptoms which should lead the surgeon to suspect a postoperative thrombosis of the portal vein are prolonged, severe abdominal pain, abdominal distension, increased white blood and platelet counts, and an increased sedimentation rate. Heparin and dicoumarin are advocated as

useful therapeutic agents in the prevention and management of this complication.

PHYSIOLOGICAL EFFECTS OF SPLENECTOMY

The introduction of a detailed review of the various physiological changes alleged to result from splenectomy would be superfluous in this paper. Suffice it to say that certain of the changes, such as a moderate secondary anemia, are due in part at least to the loss of blood at operation and are of only transitory import. Pfeiffer and Smyth have called attention to certain changes manifested in the blood picture which persist only for several months and are inconsequential. The remaining changes, such as those indicative of a disturbance in the metabolism of iron, are understandable, and that these various changes are evident for only a few weeks is also understandable in view of the fact that the function of the spleen is taken over by other organs of the reticuloendothelial system. The color of the bone marrow is said to change from a yellow, fatty appearance to a red hyperplastic type because of a lack of the restraining influence of the spleen. It is in no wise apparent that this makes any difference to the welfare of the individual.

MORTALITY RATE

If the question of when and by whom the first splenectomy was performed has a rival on the score of multifarious and widely divergent opinion, it must be the question of the mortality rate from splenectomy. The mortality rates for variously reported series of splenectomies range all the way from 100 (Russell, and also a report of the National Research Council) to 0 per cent (Grove). On the whole, however, splenectomy has always been attended by a mortality rate of sufficient proportions to warrant its being regarded respectfully and as a surgical procedure of the first magnitude. It is manifestly difficult to obtain from the literature, an accurate account of the mortality rate from splenectomy because of the inherent tendency of operators to report only their successful results. In any event, the over-all mortality rate is undoubtedly lower today than that of 20, 15, or even 10 years ago. This is due to a combination of factors including the steady improvement in diagnostic methods, a better understanding of the indications, better preoperative and postoperative care of the patient, better operating facilities, including anesthesia, and better training and organization of medical personnel. The following references will serve as a fair index of the trend in mortality rate from splenectomy.

INTERNATIONAL ABSTRACTS OF SURGERY

TABLE I. — SUMMARY OF CASES.

Case	Sex	Age	Admission Date	Admitting Diagnosis	Established Diagnosis	Date of Splenectomy	Comments
1	M	45	11-14-42	Banti's disease	Banti's disease	10-27-42	Patient well, 3 years postoperatively.
2	M	20	11-16-42	Intracranial injury	Intracranial injury and ruptured spleen	11-16-42	Patient died of concomitant intracranial injury 10 hours postoperatively. Because of apparent persistence of tenderness in the right side, a right rectus incision was made. The spleen was removed without difficulty through the right rectus incision.
3	M	25	12-27-42	Wounds, multiple	Ruptured spleen	12-27-42	Patient injured in airplane crash. Recovery complete.
4	M	21	3-20-43	Gastritis, acute	Rupture of spleen, delayed.	3-20-43	History indicated injury from blow over spleen area 3 months previous to admission to hospital. Recovery complete.
5	M	51	4-14-43	Undetermined tumor, abdomen	Cyst, spleen (Fig 2)	4-22-43	Recovery complete. Large solitary true cyst. (Fig. 2)
6	F	23	5-8-43	Ruptured ectopic pregnancy	Ruptured spleen, spontaneous	5-8-43	Recovery complete. No history of any antecedent trauma could be elicited from the patient.
7	M	22	8-7-43	Ruptured spleen	Ruptured spleen	8-7-43	Motor scooter accident. Patient was thrown against a rust steel cable which struck him over left lower posterior thorax.
8	M	36	8-20-43	Banti's disease	Hodgkin's disease	20-10-43	Patient's response to splenectomy was indifferent. Pronounced anemia persisted. Lived until 6-22-44, 8 months and 5 days from date of splenectomy. Postmortem examination revealed Hodgkin's disease of mediastinum, abdomen, and liver. On the basis of the autopsy findings, diagnosis was changed to Hodgkin's disease.
9	M	20	10-11-43	Purpura hemorrhagica	Purpura hemorrhagica	11-4-43	Recovery complete. Blood platelet count rose from 100,000 preoperatively to 500,000 postoperatively.
10	M	20	1-4-44	Ulcer duodenum perforated	Ruptured spleen, delayed (Fig 3A)	1-4-44	Because of erroneous preoperative diagnosis, right rectus incision was made. Spleen was removed without difficulty through this incision. Upon close questioning patient recalled having been struck on the left lower part of his chest, 2 weeks previously, by a thrown baseball.
11	M	30	2-24-44	Jaundice, hemolytic	Jaundice, hemolytic	5-11-44	Gall bladder contained stones. Patient underwent medical treatment with indifferent response for period of approximately 6 months prior to splenectomy. Recovery complete.
12	M	28	2-28-44	Banti's disease	Banti's disease	3-28-44	Recovery from operation uneventful. Liver noted to be small and nodular. Hematemesis was a pre-operative symptom. Patient died 12-45, almost 21 months following splenectomy.
13	F	11	3-20-44	Banti's disease	Banti's disease	4-21-44	Patient living and well 21 years after splenectomy. Spleen was 6 times normal size.
14	M	32	4-5-44	Banti's disease	Hodgkin's disease (Fig 1B)	4-11-44	Spleen weighed 1,950 gm. Histopathological examination revealed findings characteristic of Hodgkin's disease. This patient died suddenly 6-22-44, 10 weeks following splenectomy. Post-mortem findings indicated: (1) Hodgkin's disease of the abdominal and mediastinal lymph glands and liver; (2) acute cardiac dilatation.
15	F	21	6-9-44	Thrombocytopenic purpura	Thrombocytopenic purpura	6-10-44	Recovery complete. Platelet count, 45,000 immediately preoperatively. Rose to 170,000 on afternoon of operative day; 37,000 on ninth postoperative day. On 1st year following operation, patient was symptom-free.

In 1880, Russell reported a mortality of 100 per cent for rupture of the spleen in a series of 28. The number of patients upon whom a splenectomy was done is by no means clear from Russell's report. In 1900, Bessel-Hagen (13) reported 37 splenectomies for ruptured spleen with 20 recoveries and 17 deaths, a mortality rate of 47 per cent. Bessel-Hagen's entire series comprised 360 splenectomies for a variety of causes, with 138 deaths, or a 38.5 per cent general

mortality. In 1907, Berger collected from the literature and reported a series of 135 splenectomies with a mortality rate of 38.7 per cent. In 1908, George Ben Johnston reported 108 splenectomies for rupture with 51 deaths, or a mortality rate of 40 per cent. Johnston's series comprised 708 splenectomies with an over-all mortality of 27.4 per cent. In 1908, Lotch reported 138 cases with a mortality of 37 per cent. In 1909, Brog-sitter found the mortality rate to be 35.3 per cent

PUGH: SPLENECTOMY, WITH REFERENCE TO HISTORICAL BACKGROUND

in a collected series of 203 splenectomies. Willis, in 1919, found that the mortality rate for splenectomy for traumatic rupture was 28.8 per cent. Buxton, in 1922, reviewing cases up to that time found the mortality rate for all causes to have been 28.8 per cent. Beer and Rosenthal, in 1926, reported 90 splenectomies in which there were 38 deaths, or a mortality rate of 31.1 per cent. In 1926, Quenu estimated the general mortality rate for adults above 20 years of age to be 32 per cent and for individuals under 20 years of age, 14 per cent. In 1928, Connors reported 39 cases with a mortality of 40 per cent. In 1930, Dretzka reported 27 cases with a mortality rate of 33.3 per cent. In 1943, Roettig *et al.* reported 22 ruptured spleens in the city of Columbus, Ohio over a 12 year period. Eleven (11) splenectomies were done, with 1 death, a 9 per cent mortality. Of the 7 untreated patients, 6 died, a mortality rate of 85 per cent. Four (4) traumatized spleens were packed with no deaths. For the whole series there were 7 deaths among 22 cases, or a mortality rate of 31.8 per cent. For the entire 1,003 splenectomies performed at the Mayo Clinic over a period of 40 years, reported by Pemberton and Kiernan in 1945, the over-all mortality rate was only 9.4 per cent. Since 1941 there has not been a single operative death from splenectomy at the Lahey Clinic, Boston, Massachusetts.

In a manual entitled "Abdominal and Genito-Urinary Injuries" published in 1942 under the auspices of the National Research Council and intended as a guide for service doctors, it is stated, on page 96, that splenectomy for splenic trauma "in the experience of the American Expeditionary Force in the war of 1917 to 1919, was associated with a mortality of practically 100 per cent." In contrast to this, suffice it to say that the best statistics available at this time would indicate that the mortality rate from splenectomy in the Armed Forces during World War II was between 10 and 20 per cent. Complete data for splenectomy in the Navy are not available at present; however, for noncombat injuries, the Navy statistics indicate that from 1942 to 1944, there were 61 splenectomies for ruptured spleen with 5 deaths, or a mortality rate of approximately 8 per cent.

During 26 months, from 1942 to 1944, the author performed 15 splenectomies for a variety of causes (see Summary of Cases) with 1 death, or a mortality rate of 6 per cent. Actually, however, to register this case as a debit on the splenectomy ledger is not only to "lean over backwards" but indeed to vitiate statistics, since it was wholly self-evident that the major disability,

and that responsible for death, was a concurrent severe intracranial injury associated with fractured skull.

SUMMARY

1. The literature bearing upon splenectomy past and present, has been reviewed.
2. The various functions ascribed to the spleen have been enumerated and briefly commented upon.
3. The conditions for which surgical removal is indicated have been discussed with special reference to diagnosis and the rationale of splenectomy.
4. The mortality rate reported by various individuals of an earlier era has been compared with the more modern reports.
5. Photographs and drawings depicting several splenic disorders and illustrating anatomic details of importance surgically, as well as rendering understandable certain clinical phenomena, are published.
6. A series of 15 splenectomies with their respective indications is reported.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Clarkson, P., Wilson, T. H. H., and Lawrie, R. S.: The Treatment of Jaw and Face Casualties in the British Army. *Ann. Surg.*, 1946, 123: 190.

The authors present an account of the treatment and results in 1,000 jaw casualties which were treated in the North African and Italian campaigns prior to November, 1944. Of these 1,000 cases, 700 were the result of missiles, and 50 of these were major pharyngeal or palate wounds. The remaining 300 were closed wounds and were due for the most part to vehicle accidents or brawls.

The author divides the treatment of the maxillo-facial casualty into three fundamental periods, the first of which is the early treatment, next the intermediate treatment, and finally the late treatment. In the early phases, the problem is chiefly one of dental fixation. The associated soft tissues should be closed early, that is, up to 36 hours. The dead tissue should be removed, although a minimum amount of tissue should be sacrificed. A cosmetic closure should be effected in so far as possible, and then penicillin should be given. (The author states that he has had no fewer bony infective complications since he has used penicillin.) In the upper pharyngeal wounds the track should be cleaned and closed. In the lower pharyngeal wounds there is usually more infection but he still believes that cleansing the wound and closure is the treatment of choice. In early comminuted mandibular fractures he removes only the detached or infected bone. He does not believe in dependent prophylactic drainage. In antral lesions a nasal antrostomy is done; radical surgery and closure with the minimal sacrifice of bone completes the phase. In all cases early fixation of the fragments is advised except when there is an inordinate amount of edema of the tongue or nasal obstruction, for then swelling and the possibility of suffocation are too great a hazard.

Wire fixation was used in the majority of cases and was found to be most satisfactory. The problem of an airway presented itself very seldom. A complete upper respiratory obstruction or a gross intraoral obstruction was the only condition necessitating tracheotomy.

The problem of removing teeth located in the fracture site is still unanswered, but the authors believe that the teeth should be left in place if they contribute to the maintenance of the reduction, with the idea that they can be removed subsequently.

Usually the patients are kept on intravenous feedings for 2 or 3 days. There were 4 cases in which gastrostomy was done and the local treatment consisted chiefly of special attention to oral hygiene.

In the intermediate care the problem resolves itself into the treatment of the infective complications of the bones and teeth and definitive fixation. Fixation with splints, as mentioned, is most successfully done by the use of wire. Sectional cast silver closed caps and acrylic caps have been used but for the most part they are cumbersome.

Circumferential wiring was done in 45 cases with fixation for from 4 to 6 weeks. Extraoral Roger Anderson pins were used in 15 cases, 8 of which had infections around the pins. This type of fixation was not solid enough to prevent subsequent deformity. Interosseous wiring was used in 15 cases and was uniformly satisfactory in the treatment of edentulous posterior fragments in linear closed fractures.

Postoperatively, the most common cause of fever was infected bone. If the wound is not healed in 4 or 5 weeks, the likelihood of infected bone is sufficient to warrant surgical exploration. If the wound does not heal in 8 weeks, a wide incision is made with removal of questionably involved bony fragments and drainage.

The problem of secondary hemorrhage can be controlled almost uniformly by packing. In 6 cases the uncontrolled arterial bleeding was stopped by ligation of the ipsilateral external carotid artery.

The late treatment for the most part was concerned with bone grafts, the correction of scars, epithelial inlays, and trismus. Cancellous chip bone grafts were used in 14 cases and it was found that a gap of 1 cm. was united in 32 days, while one of 6 or 7 cm. was united in 90 days. An iliac donor site was found to be simple, safe, and certain.

Scar contractures were usually treated from 1 to 4 weeks after final healing of the wound.

Epithelial inlays were used for the most part to deepen the buccal sulcus.

The problem of trismus was treated prophylactically by the use of chewing gum and a wedge, and, if persistent, by dilatation under anesthesia.

The results in 110 cases of fracture of the horizontal ramus revealed that a severe comminution delayed union only about 2 weeks; that these cases often needed sequestrectomy; that early surgery, i.e., within 48 hours, reduced the incidence of infections; that soft tissue damage is not important in the rate of healing of the bones; and that early care by untrained personnel resulted in three times as many late infections.

Again, in 190 cases of angle fractures the soft tissue injury was not related to the rate of union; non-reduction of the posterior fragment delayed union.

Three weeks of occlusal fixation of 128 condylar fractures followed by full function resulted in no cases of trismus.

INTERNATIONAL ABSTRACTS OF SURGERY

Eighty-nine incomplete fractures were not treated by fixation, but simple closure of the mucous membrane was done, without incident in every case.

It was observed among 220 maxillary fractures that their importance was chiefly dependent upon their complications; namely, eye damage in 25 per cent of the cases, major hemorrhages in 10 per cent of the cases, and fracture of the anterior cranial fossa with brain injury which, though very uncommon, caused two-thirds of the deaths in the entire series.

For antral maxillary fractures, minimal removal of tissue and bone, nasal antrostomy, and closure of the soft tissue when possible were done.

In fractures of the maxilla, nasal obstruction was often complete enough to warrant a serious consideration of tracheotomy. However, by waiting from 5 to 10 days for the preliminary edema to subside and then effecting intermaxillary fixation, tracheotomy was avoided and therefore this was the preferred procedure. In floating maxillary blocks, a tracheotomy with vertical blocks was used.

Antral infections occurred in 15 per cent of the cases. In only 2 per cent of these maxillary fractures was a Caldwell-Luc operation needed.

Among the 1,000 cases 33 patients died. Four of the deaths were not due to the fracture. Fourteen deaths were due to the brain injury and the remaining 15 resulted from the maxillofacial injury. The early deaths in the last group were the result of hemorrhage and suffocation; the late deaths were due to lung complications. LOUIS T. BYARS, M.D.

EYE

Somerville-Large, L. B.: An Operation for Posterior Route Extraction of Intraocular Foreign Bodies. *Brit. J. Ophthalmol.*, 1946, 30: 208.

In the present article, the author describes a new operation for posterior route extraction of intraocular foreign bodies, which he employed in 24 cases.

With this procedure, the sclera is opened with a trephine, the area of the trephine hole in the choroid is coagulated by diathermy, and no scleral sutures are used. After the 1.5 mm. trephine is made (with care to avoid injury to the choroid), the choroid is coagulated through the trephine hole. The tip of the magnet is made to enter the trephine hole and the power is switched on for periods of from 2 to 4 seconds. The magnet is applied for a total of 15 minutes before it is decided that the foreign body is non-magnetic or too embedded. After conjunctival sutures are inserted, penicillin and atropine are instilled, and both eyes are closed.

If a diathermy apparatus is not available, the choroid can be scarred through the trephine hole with the actual cautery.

The advantages of this procedure are as follows: the foreign body is a powerful magnet point as near the num choroidal scar, and the absence of postoperative fundus hemorrhages and vitreous opacities. JOSHUA ZUCKERMAN, M.D.

O'Donovan, W. J., and Michaelson, I. G.: Epidemic Keratoconjunctivitis Associated with Skin Lesions. *Brit. J. Ophthalmol.*, 1946, 30: 193.

The authors discuss the association of skin lesions with epidemic keratoconjunctivitis. They point out that this association has not been previously reported in the literature.

In 33 cases the condition was associated with the following affections of the skin: seborrheic dermatitis, 18 cases; severe acne, 2 cases; chronic blepharitis, 6 cases; impetigo, 2 cases; severe acne and impetigo, 1 case; dermatitis of the ear lobe, 1 case; arsenical dermatitis, 1 case; and syphilis barbae, 1 case. It will be noticed that most of the lesions were of the seborrheic type.

Thirty-three of a series of 66 patients with keratoconjunctivitis had a concurrent affection of the skin; of these, 18 had an associated seborrheic dermatitis of the scalp or of the face which, in most cases, was ipsilateral. The skin lesions usually preceded the ocular condition.

The analogous nature of the skin lesions in herpes simplex, herpes zoster, and in certain cases of epidemic keratoconjunctivitis is suggested.

Cockburn, G.: Ocular Cysticercus Cellulosa. Report of a Case of Parasite in the Vitreous. *Brit. J. Ophthalmol.*, 1946, 30: 65.

The author reports a case of ocular cysticercus cellulosa in the vitreous.

The patient stated that he first noticed a fog in front of his right eye and later an object "shaped like a pear-leaf" which had a "stem" which constantly changed position. The "stem" sometimes retracted into the "leaf" only the head projecting, the remainder swelling into a mass like an "electric bulb."

Examination of the right eye revealed evidence of a perforating injury several years previously; and in the lower part of the vitreous a lustrous blue-green to russet-brown and lemon spherical cyst about 3 mm. in diameter, with a "tail" or scolex at its lower margin. The miniature tapeworm constantly changed its position. The tension was normal. No palpable cysts could be found elsewhere in the body. Examination of stools revealed ova of the lumbricoides and oxyurias vermicularis, but no segments of tania.

The cyst was removed by means of a scleral hook introduced into the vitreous. The surgical procedure corresponded to that used in magnet extraction, the wound in the sclera being surrounded by a barrage of cautery applications.

Fraser, I. G., and Scott, A. A. B.: Penicillin Treatment of Ocular Inflammation. *Brit. J. Ophthalmol.*, 1946, 30: 163.

Of 38 patients under treatment for ocular inflammation, all but 1 were hospitalized. Before starting treatment, bacteriological examination and tests for

SURGERY OF THE HEAD AND NECK

227

penicillin sensitivity were made. As a rule, treatment was commenced on admission of the patient, later cases, cultures were taken as a routine every 48 hours, and treatment was continued for a few days after negative cultures were obtained. In the majority of cases a solution of the sodium salt containing 500 units of penicillin per cubic centimeter (occasionally 250 units) was used—three or four drops being instilled every 4 hours. In 9 cases, lamellae of the calcium salt containing 180 or 100 units, were applied every 4 hours. One patient with a perforating injury received an injection of 1,250 units of the sodium salt in 0.25 cubic centimeter of sterile distilled water into both the anterior chamber and the vitreous.

Most cases of blepharitis were of long duration. Twenty patients were treated. Of these, 9 showed apparent clinical cure and 9 were greatly improved; 1 showed a marked local reaction to penicillin and treatment had to be stopped. Four patients with acute conjunctivitis were cured. Of 8 cases of conjunctivitis with a corneal lesion, 5 were cured and 3 showed no apparent response to penicillin.

Of 6 patients with keratitis or corneal ulceration, 4 were cured; 2 failed to respond to penicillin and required other treatment. Treatment of perforating injury in one patient failed.

Lamellae containing 100 or 180 units of penicillin were used in 9 cases. As compared with the solution, they have the advantage of easy storage, require no refrigeration, and are immediately available. Their disadvantage is that they are highly deliquescent, and cause some smarting and conjunctival irritation. Two patients with Eales' disease received no benefit from penicillin therapy. The tables which accompany this article are well worth perusal.

Brown, C. A.: Penicillin in Ophthalmology. The Bacteriological, Experimental, and Clinical Evidence of Its Value, Including a Personal Series of 125 Cases. *Brit. J. Ophth.*, 1946, 30: 146.

I. BACTERIOLOGY

1. Resistance of the organisms.
 - (a) Different organisms. The original classification of gram positive organisms as penicillin sensitive, and gram negative organisms as insensitive, broadly speaking, still holds good. The staphylococcus aureus and the streptococcus pyogenes are very sensitive while the pneumococcus is quite insensitive.
 - (b) Different strains of the same organism. Penicillin sensitivity varies widely with different strains of the same organism.
 - (c) Adaptation. By repeated subculture in penicillin, the resistance of the staphylococcus was increased 3,000 times, but this rapidly decreased on further subculture.

without penicillin. It is hoped that loss of acquired resistance will prove to be the rule with the majority of organisms rather than an acquired permanent fastness, as is found when sulfonamides are used.

2. Concentration of penicillin. From our present knowledge, it appears that a concentration of 2,000 units per cubic centimeter is best for the average bacterial ocular infection.
3. Acidity. The acidity of penicillin is quickly lost in acid solutions and some loss occurs even in weak acids. Boric acid and adrenalin (1:500) inhibits the activity of penicillin.
4. Incompatibility. With the exception of adrenalin hydrochloride and boric acid, it seems that all the commonly used drugs used in ophthalmology may be safely used with penicillin.
5. Effect on the tissue and cells. Penicillin is completely innocuous to the tissues and has practically no inhibitory effect on the leucocytes. The more pus striking are its effects.

II. EXPERIMENTAL EVIDENCE

1. Penetration.

- (a) External application.
 - (1) With drops of 2,500 units per cubic centimeter every 20 minutes and ointment of 2,500 units per gram every ½ hour it was found that penicillin did not penetrate the aqueous of rabbits.
 - (2) Drops or ointment of 500 units per cubic centimeter or gram went through an inflamed cornea in 14 hours.
- (b) Subconjunctival injection. By this method, penicillin appeared in the rabbit's aqueous after ½ hour, also in damaged human eyes. Small amounts reached the vitreous in ¾ hour. This is the best way to get a high aqueous concentration and to reach the vitreous sooner (¾ hour).
- (c) Intravitreal injection. Antibacterial activity of the vitreous persists for at least 24 hours. The penicillin becomes fairly evenly distributed through the vitreous in 12 hours. More than 1 injection of pure penicillin, or the use of crude penicillin, usually caused slight permanent changes in the lens, vitreous, and retina.
- (d) Intramuscular and intravenous injection.
 - (1) Minute amounts were found in the

aqueous following large doses, especially after paracentesis, but none were found in the vitreous.

- (2) Small amounts were found in the vitreous and aqueous after moderate doses.

CONTROL OF INFECTION

1. Corneal lesions.

Staphylococcus aureus pneumococcal infections of rabbit corneas were controlled by hourly drops. Treatment instituted within 1 hour of infection saves eyes that would otherwise be lost. After 24 hours, treatment was only slightly beneficial.

2. Intraocular infection.

Infection was controlled in most cases by penicillin applied locally by corneal bath, with or without iontophoresis and with little or no ill effect from iontophoresis.

3. Vitreous infection.

Without treatment all eyes were lost. If treat-

ment was delayed 24 hours, all eyes were lost. If 500 units were injected into the vitreous within 12 hours all eyes were saved.

III. CLINICAL EVIDENCE

Penicillin is the most effective treatment for acute mucopurulent conjunctivitis including ophthalmia neonatorum. Drops of 1,000 units per cubic centimeter should be used every 4 hours or oftener and continued 48 hours after apparent clinical cure. It has a real value in acute keratoconjunctivitis. Deep corneal involvement requires other care also. Superficial injuries are not likely to become infected if treated with penicillin.

Penicillin is established as the most effective therapeutic agent for acute superficial bacterial infections of the eyes. It is indicated in nonbacterial infections only if secondary bacterial infection is present or threatened. In deep ocular infections bacterial in origin, penicillin must be used in continuously high local concentrations. Its greatest value is as a prophylactic or early therapeutic measure.

LESLIE L. MCCOY, M.D.

TABLE I.—RESULTS OF PENICILLIN THERAPY IN THIS SERIES

(a) Superficial Infections					
Type of case	Total number	No of cases clinically cured	No of cases improved	No of cases not improved	No of cases of relapse
Blepharitis					
(a) Acute	14	10	4	—	—
(b) Chronic	5	1	3	—	—
Conjunctivitis					
(a) Acute	31	30	1	—	4
(b) Chronic	3	3	—	—	—
Acute keratoconjunctivitis					
(a) Moderate	33	33	—	—	6
(b) Severe	11	10	—	1	—
Non-bacterial corneal infections	0	3*	—	6	—
Superficial injuries	5	5	—	—	—

*Also had secondary (bacterial) infection.

(b) Deep Infection				
Type of case	Total number	Clinical cure (subconjunctival injection)	Improved	Not improved (drops, subconjunctival, intravitreal, parenteral penicillin)
Deep keratitis (non-bacterial)	4	—	—	4
Infection of anterior segment				
(a) Traumatic	2	2	—	1
(b) Infective	5	1?	—	2
Infection of posterior segment				
(a) Traumatic	3	—	—	2
(b) Infective	5	—	—	1

Troncoso, M. U.: Diathermy in Glaucoma. *Am. J. Ophth.*, 1946, 29: 269.

A review of the literature available on cyclodiathermy procedures precedes the author's report of his own experiments on rabbits' eyes to determine directly the physiological bases of diathermic methods. Ordinary diathermy apparatus was used to coagulate the ciliary base and processes, and observation of the results was made with the slit lamp microscope after enucleation of the eye, which was followed by micropathological examination.

The author found that both Vogt's transcleral puncture method and the nonpenetrating diathermy of Albaugh and Dunphy caused severe inflammatory reactions and affected primarily the orbicular cilia instead of the ciliary processes. The author therefore devised new surgical techniques for direct local coagulation of the ciliary base and processes. This was carried out via the posterior route through the sclera and an anterior route through the peripheral cornea. Both monopolar and bipolar electrodes were applied. A third technique, called "translimbal diathermy" was evolved, in which an electrode was used to penetrate the limbus obliquely and coagulate the ciliary bases and to leave a filtering aperture upon its withdrawal.

The author concludes that the results of diathermy of the ciliary body are in general unsatisfactory, notwithstanding several apparently successful experimental results which he obtained by means of his own technique. HUNTER H. ROMAINE, M.D.

EAR

Hall, I. S.: The Surgical Treatment of Deafness. *Irish J. M. Sc.*, 1945, Ser. 6, 80.

The operation described follows closely the lines of the modified radical mastoid operation, the sole

difference being that in the modified radical operation the ossicles are left intact. The postaural approach is the author's choice.

The pedicle flap is an important part of the operation; it is taken from the roof and posterior aspect of the external auditory meatus, and is raised from the bone complete with *membrana flaccida*. The *incus* and the head of the *malleus* are removed. This gives complete exposure to the labyrinth. With the use of a dental drill an opening, from 3 to 4 mm. long by about 2 mm. broad, is made as far as possible over the ampulla of the horizontal canal as it enters the utricle. The flap is then placed in position and secured with paraffin packs, and the wound is closed in the usual manner.

In the selection of patients, it is better that they be young. The patient should not be too deaf as only 30 decibels can be restored. There must be no nerve deafness, and there should have been no previous middle ear disease.

The author presents the results obtained in 80 patients, all of whom were operated upon more than 5 months previously. The average percentage of improvement is 58.4 per cent.

JOHN F. DELPH, M.D.

Farquharson, J. M.: The Masking Effect of Sulfonamide When Used in the Treatment of Acute Otitis Media. *J. Lar. Otol.*, Lond., 1945, 60: 269.

A comparative study was made of the cases of acute otitis media occurring in the wards of the Edinburgh Royal Infirmary from 1937 (when sulfonamide was introduced) until 1944. The cases occurring in the previous 8 years were used as a comparison.

In presulfonamide days, 29 per cent of patients with otitis media developed mastoiditis; since then, only 13 per cent have developed mastoiditis.

For some time now the otologist has been aware that a change in the once familiar signs and symptoms of acute mastoiditis can occur after the administration of one of the sulfonamide drugs.

The drug, by its marked analgesic and antipyretic properties, tends to obscure the clinical picture, and often gives rise to a latent course of the disease that is responsible for the overwhelming pathological changes we so often see.

It is a matter for profound meditation that the drug which has produced such miracles in the treatment of otitic meningitis is the same drug which, used misguidedly, is indirectly responsible for the development of the disease itself—by masking symptoms that would have indicated surgical intervention.

The exhibition of sulfonamides is liable to change the ordinary case into an infection which is identical with that produced by the pneumococcus, type III; furthermore, how significantly altered must be our judgment when the two factors are combined; namely, the insidiousness of the pneumococcus and the masking effect of the sulfonamide.

At this juncture must be mentioned the masking effect of the drug when used after operation to control a febrile reaction, the cause of which had not been diagnosed.

Complications, when they did occur, were either completely hidden or sufficiently masked to distort the criteria for more extensive surgery. For this reason, therefore, following simple mastoidectomy the drug should not be given in uncomplicated cases.

In the case of lateral sinus thrombosis or petrositis, the limit of surgical measures must be reached before the drug can be safely given.

In the last 8 years an appreciable deterioration in hearing has been noticeable in the cases of otitis media passing through the outpatient department of the Edinburgh Royal Infirmary. In the absence of other factors, this must be attributed to the masking effect of the drug causing delayed drainage from the middle ear. This may promote an adhesive inflammatory change or, as suggested by Kopetzky, may be due to a hydrops of the labyrinth as the result of a chemical reaction between the perilymph behind the oval and round windows, and the purulent contents of the middle ear. Only promptness in the relief of this hydrops by drainage of the ear will save the hearing; if delayed, permanent changes may occur in the cochlea.

The author states that cases of acute otitis media are now arriving at the Outpatient Department much later than in other years. A number of the patients seen are those who have failed to be cured by the "box of white tablets and ear drops" supplied by their doctor. For this reason operative drainage has occurred as late as from 3 to 4 months after the acute attack. This has caused an increase in the number of cases which have developed chronic otitis media.

A series of 8 clinical records is submitted to illustrate the masking effect of the sulfonamides.

JOHN F. DELPH, M.D.

Youngs, N. A., and Lindsay, J. R.: Suppurative Labyrinthitis. *Ann. Otol. Rhinol.*, 1946, 55: 43.

The case presented by the authors is an example of the complicated clinical picture which may accompany a petrous pyramid suppuration, and illustrates the limitations of chemotherapy in its present form.

NOAH D. FABRICANT, M.D.

Day, K. M.: Hydrops of Labyrinth (Ménière's Disease). Diagnosis and Results of Labyrinth Surgery. *Laryngoscope*, 1946, 56: 33.

Successful results from labyrinthine surgery in 19 consecutive cases of unilateral hydrops of the labyrinth have convinced Day that this type of surgery is no longer experimental, but the best kind of treatment for this condition. Moreover, he believes that it should replace the intracranial procedure of section of the eighth nerve.

The author now feels fully justified in advising operative interference for those cases of hydrops of the labyrinth that do not respond to conservative

therapy or for patients who are losing enough time from their occupation to be considered economically handicapped.

NOAH D. FABRICANT, M.D.

MOUTH

Steinberg, I. R., Mengoni, H. R. and Oscar Vigilino, J. R.: Tuberculous Ulcer of the Tongue (*Úlcera tuberculosa de lengua*). *Prensa med. argent.*, 1946, 33: 576.

A white male, 52 years of age, had suffered an acute attack of lung trouble at the age of 16, and since then has had chronic bronchorrhea, at times quite abundant, but he had continued to work at various occupations, as farm hand, milkman, baker, and garage man. In July of last year, pains, accompanied by cough and mucopurulent expectoration, occurred in the left side of the chest and then changed over to the right side and the patient lost 10 kgm. (22 lb.) in weight. It was apparently about the time of the pain attacks that the patient noted a small firm nodule in the anterior dorsum of the tongue, somewhat to the left side, which seemed to increase in size as the chest condition became worse; at times, however, it disappeared entirely.

About 6 months later the lump ulcerated, continuing to increase in extent and depth until at the last examination the lesion was a huge, punched out, sluggish ulcer with irregular, edematous edges extending almost all the way through the tongue and terminating in a lardaceous looking irregular floor (Fig. 1).

Physical and roentgenological examination uncovered an excavating, acinoexudative pulmonary tuberculosis predominantly on the left side; the sputum was positive for tubercle bacilli; and biopsy

confirmed the tuberculous nature of the tongue lesion itself.

Rapid improvement has taken place with rest, good food, vitamins, especially B₁ and nicotinic acid, general tonics, topical cocaine or pantocaine before eating, and, finally, chrysotherapy.

It is thought that with the absence of all evidence of etiological trauma in this practically edentulous patient, this lingual lesion arose hematogenically as a tuberculous gumma, closely bound up with the pulmonary involvement; the tongue lesion tended to influence the pulmonary condition unfavorably, because it created difficulty in eating, and therefore the whole process constituted a true vicious circle.

JOHN W. BRENNAN, M.D.

NECK

Mahaux, J.: Acute Hyperthyroid Crises. Physiopathological Study (*Les crises aiguës des hyperthyroïdies. Étude physiopathologique*). *Rev. sci. med.*, 1945, 16: 21.

Hyperthyroidism evolves in stages, beginning with an initial traumatism in a subject constitutionally predisposed to a disease in which an abnormal amount of thyroxine is mobilized, continuing in a stage in which the neuroendocrine body mechanism becomes adapted to a metabolism at an elevated level under excessive thyroid stimulation, and terminating under this precarious thyroid balance in cardiac failure or general incapacity. In the later stages of the illness any one of many stimuli—a mild infection, fatigue, pregnancy, emotional stress, slight trauma, or interruption of iodine therapy—may precipitate a so-called thyroid crisis which is often terminal. Such a crisis, however, is most frequently seen following thyroidectomy.

The cause of the thyroid crisis is believed to be a sudden cessation of thyroid secretion. Premonitory signs include anorexia, persistent insomnia, great emotional instability, occasionally vomiting and diarrhea, pain in the thyroid gland, a rapid increase or decrease in the volume of the gland, an accentuation of exophthalmos, and intense motor agitation. Icterus, severe hyperpyrexia, and a rapid pulse also appear. The electrocardiogram discloses a slowing up of the intracardiac conduction. Cachexia develops rapidly. The iodine levels in the blood fall. If death supervenes, autopsies reveal an indurated gland, a parenchymal hyperplasia, and an almost complete absence of colloid.

In the patient with chronic hyperthyroid disease the colloid reserve is actively resorbed without having been reconstituted and is immediately dispersed in the blood. The iodine level of the gland falls, and the thyroglobulin is found to be poor in thyroxine. Normally, only a certain portion of the thyroxine is used to resynthesize thyroxine; the rest is excreted. One sees a negative iodine balance, an "iodine diabetes," in which the excretion of iodine is enhanced to the point of complete elimination. The treatment of chronic Basedow's disease with

Fig. 1

Iodine based on the previous considerations is well established and has reduced somewhat the frequency of thyroid crisis. However, there are other factors to consider. There exists in each acinus a delicate balance between intravascular secretion and secretion into the blood, and if there is a preponderance of the latter function, the cells cannot build up reserve colloid and, at length, in spite of sufficient iodine, acute depletion occurs.

The treatment of the acute thyroid crisis has generally been the administration of large doses of iodine, but this has not proved satisfactory. Two cases are presented which ended fatally despite iodine and additional symptomatic therapy. In 1925 an acute thyroid crisis was first treated by giving thyroxine intravenously, by Kessel and Hyman, with clinical resolution of the symptoms and a return to the chronic state of mild hyperthyroidism. As far as is known to the authors, this treatment has not been put into general practice since that time, and 3 cases are presented in which thyroxine was used following the failure of iodine therapy. In a typical case, that of a crisis precipitated by a serum reaction in a case of chronic Basedow's disease, the patient was given iodine for 12 days without effect, and responded promptly and favorably to thyroxine. Contrary to popular opinion, thyroxine is not the exciting agent but acts as a stabilizing agent in an endocrine vegetative equilibrium (adapted to an elevated level of thyroid activity) which is disturbed by the acute failure of thyroid secretion.

Formerly one-third of the cases of thyroidectomy resulted in the development of an acute thyroid crisis. From 12 to 30 hours after operation agitation, an exacerbation of the exophthalmos, insomnia, temperature elevation, and cardiovascular collapse were observed. The height of the symptoms appeared 2 or 3 days after the resection, and if the patient could pass this critical period, the prognosis became better. The cause of the postoperative crisis appeared to be the sudden lack of thyroxine due to suppression of the thyroid parenchyma; an increased demand of the organism for thyroxine was met only by a greater depletion of the hormone. Many surgeons still incorrectly believe that the trauma of thyroidectomy liberates an excess of thyroxine into the general circulation and that excess thyroxine produces the symptoms. To controvert this is the observation that crises cannot be produced in a patient with hyperthyroidism by thyroxine injections. Biochemical studies have proved that thyroxine levels are low in severe post-thyroidectomy cases—this "hypothyroxemia" is responsible for the postoperative crises. This opinion is held by many authorities.

Systematic preoperative and postoperative thyroxine administration is indicated as part of the surgical treatment of hyperthyroidism. A series of 175 cases were surgically treated and 4 mgm. of thyroxine were injected immediately after operation without the appearance of a single crisis. It is important to

note that satisfactory preoperative preparation does not insure against a postoperative hypothyroxemic crisis—"the destiny of the hyperthyroid operative cases is actually obscured by a cloud of uncertainty." From 1 to 2 mgm. of thyroxine are given at the time of anesthesia, followed by the administration of from 2 to 4 mgm. of the same drug immediately after intervention, and then by from 1 to 2 mgm. every 8 hours for 3 or 4 days; this avoids the danger of a crisis. From 12 to 60 hours after the thyroxine injections have been terminated there is a transitory increase in the pulse rate but this mild hypothyroxemia should not cause concern. Eventual postoperative complications (hemorrhages, postoperative pneumonia, laryngeal difficulty), which are not to be confused with an acute crisis, occasionally appear, but they are generally not severe. It goes without saying that surgery is contraindicated in the presence of a thyroid crisis.

A resection of the cervical sympathetic chain, complete or partial, brings on an immediate exaggeration of symptoms, even a thyroid crisis. X-ray irradiation of the thyroid does not obviate the dangers of a crisis, in fact it may even bring on hypothyroxemic shock; the use of thyroxine does away with the use of irradiation.

The role of the thyrotropic hormone of the hypophysis is significant in the etiology of the thyroid crisis. Several authors are quoted who report the production of a crisis in a hyperthyroid patient by the injection of thyrotropic hormone. The administration of thyroid over a long period of time causes an increase in the stimulating activity of the pituitary gland, and, should thyroid administration be stopped (as in the course of treatment of obesity), a thyroid crisis may be precipitated due to excess thyrotropic activity. One such case is reported which ended in death. It is concluded that the hypophysis functions to maintain a constant supply of thyroid hormone; in hyperthyroid states the extent of this control is greater in maintaining greater thyroid activity. Excess thyrotropic hormone following the lowering of thyroid activity, as after thyroidectomy, plays a part in the production of a thyroid crisis; therapeutic thyroxine allows for hormonal adjustments to occur and for this reason there is a reduction of the danger of a crisis to a minimum.

It is concluded that the adequate preoperative and postoperative administration of thyroxine can prevent the sudden neuroendocrinological disbalance which is manifested by hypothyroxemia and the acute thyroid crisis. PHILIP B. CHASE, M.D.

Halpert, B., Cavanaugh, J. W., and Keltz, B. F.: Structural Changes in the Thyroid Glands of Patients Treated with Thiouracil. *Arch. Path., Chic.*, 1946, 41: 155.

Seven patients with marked signs and symptoms of exophthalmic goiter were so treated as to provide material for a study of the effects on the thyroid gland of thiouracil alone, of a strong solution of

iodine (U.S.P.) followed by thiouracil, and of thiouracil followed by a strong solution of iodine (U.S.P.). On all, bilateral subtotal thyroidectomy was performed in one or two stages. Two patients received preoperative therapy with thiouracil only; 3 were treated with a strong solution of iodine (U.S.P.) followed by thiouracil, and 2 were treated with thiouracil followed by a strong solution of iodine (U.S.P.).

In the glands removed following the administration of thiouracil only, the acinous content stained lightly and was decreased or absent and the cells lining the acini were low or tall columnar. These changes were quite similar to those seen in the thyroid glands of untreated patients in an active state of hyperthyroidism. In the patients treated with a strong solution of iodine (U.S.P.) followed by thiouracil, the thyroidectomy was performed in two stages and the former drug was used prior to the first surgical procedure and thiouracil prior to the second. Following the administration of thiouracil the cells of the acini changed from cuboidal to columnar, and the colloid disappeared or decreased in density and became vacuolated and scalloped. In the glands removed after the administration of thiouracil followed by the strong solution of iodine (U.S.P.), a refilling of the acini with colloid could be observed together with a change of the lining cells from columnar to low columnar or cuboidal.

According to these observations, the acinous colloid diminishes in quantity and density or disappears under the influence of thiouracil. The variance between structure and function of the thyroid gland following the administration of thiouracil supports the assertion that thiouracil inhibits the production of new colloid but does not interfere with the use of the available colloid.

E. A. GORVETZ, M. D.

Moore, F. D.: Toxicity of Thiouracil. *J. Am. M. Ass.*, 1946, 130: 315.

In order to evaluate the incidence of severe toxic manifestations of thiouracil therapy, an accumulation of data on the experiences of 24 clinicians in 10

American clinics and 1 English clinic, are presented, a total of 1,091 patients are included in the material.

The clinics and number of cases were: Barnes Hospital and Washington University School of Medicine, 62; Beth Israel Hospital, 63; Boston City Hospital and Massachusetts Memorial Hospitals, 225; Jefferson Medical College and Hospital, 55; Johns Hopkins Hospital, 45; Lahey Clinic, 196; Massachusetts General Hospital, 99; Mayo Clinic, 38; New York Hospital, 125; Presbyterian Hospital, 88; University College Hospital Medical School (London), 64; University of California Medical School, 31.

Treatment was given for a period ranging from 2 weeks to 2½ years (in the majority of cases for from 2 to 8 months), with a dosage of from 0.5 to 0.8 gm. per day for from 3 to 7 weeks, or until the basal metabolic rate was normal, after which the dosage was reduced or the patient was operated on.

The hematological changes were stressed, rather than the tabulation of all the symptoms, as the leucocyte changes were considered most serious.

The most important data were: the incidence of total deaths, 0.7 per cent of 1,091 cases; the deaths due to drugs, 0.5 per cent of 1,091 cases; agranulocytosis, 1.7 per cent of 1,091 cases; the deaths from agranulocytosis, 26 per cent of 1,091 cases; leucopenia, 3.4 per cent of 781 cases; gland enlargement, 2 per cent (the author gives 5 per cent but cites 10 among 458 cases); drug fever, 5 per cent of 781 cases; and miscellaneous reactions, 2 per cent of presumably 1,090 cases.

A table is given of the details of the 19 cases of agranulocytosis. The 2 per cent of miscellaneous reactions are briefly described and discussed.

The total incidence of severe reactions which necessitated the stopping of treatment with thiouracil was between 8 and 10 per cent.

The most dangerous period, from the viewpoint of leucopenia, was between the fourth and eighth weeks from the start of treatment, although it may be earlier if the drug has been given previously, regardless of whether or not there were untoward reactions at that time.

CLINTON H. THAMES, M. D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Albritten, F. F., Jr., and Maltby, G. L.: Causalgia Secondary to Injury of the Major Peripheral Nerves. *Surgery*, 1946, 19: 407.

Causalgia of the type described by Weir Mitchell has been seen in a considerable number of cases (67) seen at Ashford General Hospital, White Sulphur Springs, West Virginia, during a twelve month period. The lower extremity was involved in 44 cases, and the upper extremity in 23. The seat of maximum pain has been in the posterior tibial and median nerves in all instances.

The treatment given was to first block the sympathetic fibers by procaine block of the sympathetic ganglia, and if this afforded marked relief to proceed to a sympathectomy. On rare occasions patients received permanent relief from a single sympathetic block. Both the muscle splitting extraperitoneal approach for the removal of the second and third lumbar ganglia, and the thoracolumbar operation described by Smithwick have been used. The Smithwick procedure has been used for sympathectomization of the upper extremity. These procedures were carried out in 30 cases—22 with involvement of the lower extremity and 8 with involvement of the upper extremity. Results were good to excellent in 23 cases; 2 patients showed no relief despite technically satisfactory sympathectomies.

The authors believe that the procedure should be of sufficient extent to include the area of injury as well as the area of symptoms and that early sympathectomy will, in the vast majority of cases, relieve the symptoms of disease and prevent the profound disabilities of disuse.

JOHN W. EPTON, M.D.

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Fleminger, J. J., and Smith, M. C.: Acalasia of the Esophagus following Depressed Fracture of the Base of the Skull. *Lancet*, Lond., 1946, 1: 381.

A 16 year old girl developed a total inability to swallow liquids or solids following a head injury in which there was a comminuted depressed fracture with a subdural hematoma in the right occipital region. At operation, depressed bone was removed from the right cerebellar fossa together with about a third of the foramen magnum, which was involved along with the right hypoglossal canal in the fracture.

Two months after operation an attempt was made to induce normal swallowing by suggestion with the patient under intravenous sodium amylal anesthesia. This was unsuccessful. Two and one-half months after surgery, x-ray examination showed the meal to be held up both at the upper and lower ends of the esophagus, indicating an achalasia of the cricopharyngeus and of the cardiac end of the esophagus.

For that reason it was decided to attempt the relaxation of these muscles with amyl nitrite. She was given an ampoule of this drug to inhale. In a very few minutes she was able to swallow a small amount of liquids and solids. Thereafter, she showed an increasing ability to masticate more normally.

The authors conclude that this patient represented a striking example of combined somatic and psychological disorder. A vicious circle initiated by physical damage, and largely perpetuated by emotional disturbance, was eventually broken, with complete restoration of function.

JOHN W. EPTON, M.D.

Devic, A., Ricard, A., and Guinet, J.: Delayed Post-Traumatic Brain Abscess (Les abcès du cerveau post-traumatiques tardifs). *Lyon chir.*, 1945, 40: 463.

A syndrome is described which is a localized brain abscess occurring years after injury, and generally long after the patient appears to have made a complete recovery. Two personal cases are presented in detail along with a brief review of the literature.

Pathologically, the abscess is usually multilocal and surrounded by a very thick capsule. Because of the heavy capsule the surrounding structures are damaged only by compression and not by spread of the inflammatory process.

The etiology is attributed to organisms brought into the brain substance on bone spicules or metal fragments at the time of the original wound. These organisms are believed to remain alive but latent for months or years in the midst of a small mass of scar tissue. Clinically there are three distinct phases: the acute injury, the more or less asymptomatic latent period, and the phase of suppuration. In the last phase there are no signs of general infection and the evidence of increased intracranial pressure is not constant. The most characteristic symptom is progressively severe localized headache. Subsequently, insomnia, vomiting, and stiffness of the neck may appear. Slowing of the pulse is rather characteristic. Other manifestations depend on the size and location of the abscess, e.g., epileptic convulsions, paralysis and sensory disturbances.

The prognosis with operation is favorable—usually recovery with a minimal localized residue. Without surgery the outcome is always fatal. For prophylaxis the use of sulfa drugs and more thorough débridement are suggested. Once an abscess has developed, excision of the whole mass is advised in preference to drainage because of the dense capsule which is usually present.

THEODORE B. MASSELL, M.D.

Scott, M.: Nontraumatic Hematomas. *J. Am. M. Ass.*, 1946, 130: 845.

The author reports the results obtained in the surgical evacuation of spontaneous nontraumatic

hematomas of the left temporal lobe. The patients presented the following symptoms:

1. Sudden onset with severe headache in 2 cases, and aphasia in the third case.

2. Progressive drowsiness.

3. Focal symptoms of an expanding lesion in the left temporal lobe, viz., partial aphasia with anomia and jargon speech; right homonymous hemianopsia; increased deep tendon reflexes on the right; Hoffman and Babinski signs on the right; progressive weakness of the right side of the body; no sensory disturbances; and shift of the pineal gland to the right.

4. The spinal fluid pressure was usually increased; the fluid blood was tinged, clear, or xanthochromic, with the total protein above normal.

Following a left exploratory craniotomy, a subcortical hematoma was found in all 3 cases in the left posterior superior temporal lobe. The clot was removed by suction, the dura closed, and the bone flap replaced. Recovery with improvement occurred in all 3 cases.

Any person, regardless of age, developing sudden headache associated with progressive focal signs such as aphasia, hemiplegia, anesthetics, or visual field defects, vomiting, and progressive drowsiness should be considered to have a space-taking lesion, possibly intracerebral hematoma. Exploratory craniotomy with evacuation of the blood clot offers the best method of treatment in cases showing progression in signs and intracranial pressure.

JOHN W. EPPON, M.D.

Tom, M. I.: Metastatic Tumors of the Brain. *Canad. M. Ass. J.*, 1946, 54: 265.

In a series of 82 cases of metastatic tumor of the brain (no patients with metastases to the dura, skull, spinal cord, or nerves were included), 18 patients, 15 male and 3 female, had their primary tumor in the lungs, 13 (all female) had their primary tumor in the breast, and 9 patients, in the bowel, while in 7 patients the tumors arose from malignant melanomas.

The various other endocrine glands and the common sites of tumor in the genitourinary tract of both sexes revealed a surprisingly small number of tumors metastatic to the brain. Metastases were found in the cerebral hemispheres of 49 patients, in the cerebellum of 23 patients, in the pituitary gland of 19 patients, and in the subarachnoid spaces of 14 patients. Multiple metastases occurred in 41 cases, and single metastases in 41 cases. The primary symptoms in the breast were almost always recognized before the symptoms of cerebral metastasis were observed, but the reverse was true in the case of lung tumors.

Of 52 cases in which complete autopsy was performed, 78.9 per cent were found to have either primary or metastatic tumors in the lungs. This high incidence of tumor in the lungs, either as the primary site or locus of metastasis, should impress upon us the necessity for thorough physical and x-ray examination of the chest whenever there is a question of differentiation of primary from secondary tumors of the brain.

JOHN MARTIN, M.D.

Ectors, L.: Mechanical Results of the Development of a Tumor in the Craniovertebral Cavity (Les conséquences mécaniques du développement d'une tumeur dans la cavité craniovertébrale). *Rn. dz.*, Par., 1945, 64: 204.

In a study of the mechanical results of tumor development in the craniovertebral cavity, the author demonstrates the effects of pressure and space limitation on the various tissues of the cranial cavity individually and as a whole. Schematic drawings illustrate a discussion of the effects of compression on nerve tissue, veins, and the cerebrospinal fluid, and the results of displacement of the brain stem. Compression of nerve tissue beneath the tumor produces a focal syndrome which is followed by the characteristic symptoms of displacement and, finally, by signs of cerebral or cerebellar hernia with peduncular or bulbar involvement and death. Some tumors of the brain stem may present a purely focal syndrome to the end. Both reversible and irreversible lesions may be produced by compression of the nerve tissue.

Early postoperative improvement is due to removal of the tumor and the secondary more protracted improvement to subsidence of the vascular disturbances and edema. The deficiency left after maximum improvement has been attained is attributable to irreversible lesions. Histological studies confirm such a course.

Extracerebral tumors cause more marked lateral displacement of the brain than intracerebral tumors. Only tumors of the frontal third produce homolateral hemiplegia by displacement of the brain stem because the frontal third projected on the orifice of the falx cerebri is thus connected with both halves of the cranial cavity. The mechanism responsible for homolateral pyramidal signs in acoustic neuromas is likewise explained.

Pressure on intracranial blood vessels may produce symptoms masking the focal effect on the nerve tissue. Reports on the effects of compression on the arteries in the cranial cavity are scarce and contradictory. Venous compression produces edema, which if limited to a small portion of the brain may cause no symptoms. Involvement of nearly an entire hemisphere is necessary to produce symptoms. Venous compression also leads to the formation of a transudate rich in proteins, with resulting marked increase in the protein content of the cerebrospinal fluid below the level of the tumor without any increase in cellular elements, the well known protein cellular dissociation syndrome.

Even greater disturbance is caused by pressure in the cavities containing the cerebrospinal fluid, and the effects are entirely different, according to whether the pressure is increased in the ependymal or subarachnoid circulation of the cerebrospinal fluid. The rachnoid circulation of the cerebrospinal fluid and the pia mater, permeable. The effects of various ventricular tumors on the pressure conditions and dilatation of the ventricles are discussed. Tumors of the subarachnoid system have an entirely opposite effect, producing edema. Thus pressure at different sites

may lead to diametrically different symptoms, namely, to hydrocephalus or edema, with not infrequently a conflict between the two. Illustrative cases are cited. The extracranial portions of the optic nerve react to pressure in the subarachnoid system, but not to intraventricular pressure because the ventricles are separated from the nerve by a bony wall. The effect of glaucoma in relieving choked disc is analogous to that of hydrocephalus on edema.

Intracranial spatial deficiency due to tumor development depends not only upon the size of the tumor but upon the degree of edema or hydrocephalus produced by the tumor. Small tumors in the aqueduct of Sylvius may cause marked early spatial deficiency, while large interhemispheric tumors of the anterior third may not produce symptoms of spatial deficiency until late in their course.

The tendency of tumors of the anterior part of the brain or the midbrain to push the brain through the tentorial orifice into the posterior cavity, and of posterior tumors to crowd the cerebellum through this orifice into the median cavity and through the occipital fossa into the spinal cavity, is discussed. Supratentorial tumors producing edema and not hydrocephalus will force the temporal lobe through the tentorial orifice which results in herniation. Compression of the veins in the neck of such hernias causes edema of the herniated portion. Tumors producing hydrocephalus without edema do not cause herniation. Cerebellar hernia produced by a similar mechanism will compress the cerebral peduncle which leads to venous congestion and frequently results in hemorrhage. Involvement of the cerebral tonsils produces the syndrome of bulbar compression.

Any measure that reduces edema will relieve symptoms, and the intravenous injection of a hypertonic solution has a marked temporary sedative effect. On the other hand, horizontal decubitus which increases intracranial venous pressure, or an enema causing prolonged congestion of the abdominal veins, will cause exacerbation of the symptoms; cough, sneezing, defecation, or emotional excitement will do this also. Any measure which diminishes the pressure in the cavity subjacent to the lesion favors herniation, as illustrated by the disastrous and frequently fatal results of spinal puncture with its aspirating effect.

EDITH SCHANCHE MOORE.

Dickmann, G. H.: Cerebral Resections (Resecciones cerebrales). *Rev. As. med. argent.*, 1946, 60: 91.

The author discusses the indications for cerebral resection, and reports 8 cases which were operated upon, 3 having been reported previously. Only 2 case reports of lobectomy for traumatic epilepsy are given; gross cicatricial lesions of the frontal lobe were found in both of these cases. A special report on the results of surgical treatment of epileptics will be published later.

Four conditions are cited in which the operation may be indicated:

The first one is cerebral tumor or inflammatory process. Here the operative mortality in competent

hands does not surpass 15 per cent, and even though definitive cure cannot always be promised, the amelioration is always greater than that obtained by simple decompression. A clinical cure of from 7 to 8 years, even in malignant tumors, amply justifies the procedure. Although tuberculomas may often be enucleated easily, the operation of intracapsular enucleation promises nothing more than a recurrence of the tuberculoma or tuberculous meningitis, since the capsule always contains tubercles in abundance.

The second condition is that in which the brain substance must be resected in order to reach more deeply seated lesions, such as tumors of the lateral ventricles or of the third ventricle, in which partial resection of a cerebellar lobe is necessary to reach the cerebellopontine angle, or in which removal of a frontal lobe is necessary to attain the region of the hypophysis, in the presence of craniopharyngiomas, or olfactory or parasellar meningiomas, or removal of the temporal or occipital lobes is necessary for deep lesions.

The third condition cited is that of traumatic epilepsy, in which the author, guided by his electric excitator (thyatron), attempts to excise all the scar tissue and even opens up the ventricles to do so. In 1 of the 2 epileptics here reported all the scar tissue could not be removed because of the contiguity of the prerolantic area and this case was the only clinical failure in the entire group. The author rather discounts the influence exerted by shallow, superficial meningeoencephalic traumas.

The fourth condition is that of deep hemorrhage which cannot otherwise be exposed and controlled.

The first case history was that of a 32 year old male with convulsive attacks, whose failing vision suggested something more than a Jacksonian epilepsy, and at operation an astroblastoma of the right frontal lobe was uncovered. Here an extensive resection of the involved lobe removed most of the tumor. Since the operation he has suffered an occasional attack of convulsions, which were largely controlled by luminal. Case 2 was that of a 37 year old female who was operated upon twice. At the first operation a flat, mushroom tumor, attached by a pedicle rather far forward on the cortex of the frontal lobe, was removed and the area was quite intensively irradiated; nevertheless, about 2 years later there was a return of symptoms (cephalgia, paresis of the rectus externus muscle of the right eye, and paresthesia) and the second operation disclosed a deep multiple cystic isomorphic glioblastoma. A resection according to the technique of Dandy removed most of the neoplasm with almost immediate relief of the paresthesia and other subjective manifestations. The patient has a clear mind and walks perfectly.

The third patient was a 25 year old male railroad worker, who began to suffer from headaches 3 years ago and eventually developed a right homonymous hemianopsia. Operation disclosed what was evidently a tumor of the left occipital lobe, which was resected with care not to disturb the optic radiations.

In the depths of this lobe a firm enucleable tumor which proved to be a tuberculoma was uncovered. The patient has since been able to continue working, but the hemianopsia has remained stationary. The fourth resection here reported was that of a 26 year old female complaining of frontoparietal cephalalgia on the left side with serious diminution of vision in the left eye growing progressively worse. Operation disclosed enlargement and tenseness of the right frontal lobe. A Dandy resection of this lobe cut through the anterior end of a firm tumor; this was then enucleated, and apparently the ventricle was opened. However, the leak of ventricular fluid ceased gradually, the wound healed, and subsequently the hemiparesis of the left leg and arm, and even the vision in the left eye improved noticeably, the patient being up and about with absolutely normal psyche a month or so later. The tumor was diagnosed as a mixed gigantocellular glioblastoma and astroblastoma. The fifth case was that of a 27 year old female complaining of headaches, diminution of vision, photophobia, vomiting preceded by nausea, and some change of psyche. Right frontal lobectomy did not entirely remove the tumor, some tissue of which was seen to extend backward out of reach. Eight months later the patient was perfectly well, the eye grounds had returned to normal, and she was able to lead her normal life. The sixth and seventh patients were those with the traumatic epilepsies already mentioned; in the first the condition was considerably ameliorated but in the other it did not improve. The seventh patient was briefly mentioned as having undergone a left occipital lobectomy for glioblastoma; at the present time he is perfectly well and able to carry on his avocation as a roving peddler. He has gained 20 pounds in weight, and the edema of his eyes has cleared up, leaving a certain amount of postdematous optic atrophy.

The author is not as much interested in the striking recovery following lobectomy with regard to the improved vision and disappearance of pareses, which may be ascribed to pressure and would tend to get better following its removal, as he is in the changes in the higher psychic functions to be expected from removal of so much of the important tissues of the brain, such especially as those represented by the frontal lobe of the cerebrum. When one tries to analyze the individual functions of a higher nature, there do not seem to be any appreciable changes in the lobectomized patient aside perhaps from a certain appreciable disproportion, a failure to exhibit the justifiable anxieties of the situation, and an absolute lack of preoccupation with the future. The emotional status seems to return to its former level; some patients are less irritable and more tolerant, and an adequate response to humorous situations is noted.

However, when the examiner ceases to scan the psychic qualities, such as intelligence, memory, attention, and moral and esthetic senses individually, and turns his attention to that something which causes each individual to differ from all others, he will note that the frontal resection has produced a

modification of the personality, which may escape the analysis of one not experienced in the problems of psychiatry and psychology. These alterations consist in an evident limitation of the complexities of thought. It is difficult to incite these patients to new activities, requiring more elaborate mental functioning. There is a relaxation in the will power, a difficulty in synthesizing thoughts and sentiments, and also in comprehending at a single glance a variety of representations, a certain amount of apathy, a fault in planning initiative, and a diminution in the power of imagination. However these individuals do not suffer disturbances of sphincter control nor alterations in the tone of the superficial or deep reflexes.

The author does not share the localization ideas of Kleist, because it was always possible that the lesion extended beyond the limits of the frontal lobe in the war casualties which he observed.

The author believes that frontal lobectomy has revealed the following facts:

1. Either of the frontal lobes is capable of carrying on satisfactorily the normal functions of both;
2. There is no predominance of function in either of the frontal lobes. A patient who has undergone a resection of the left frontal lobe is the same as one who has lost the right lobe.
3. The frontal lobe syndrome, characterized by defects of intelligence and alteration of the personality, is not the consequence of the suppression of the lobe, but of its dysfunction.

JOHN W. BRENNAN, M.D.

SPINAL CORD AND ITS COVERINGS

Elkins, C. W., and Wegner, W. R.: Newer Concepts in the Treatment of the Paralyzed Patient Due to Wartime Injuries of the Spine—Neurosurgical Complications. *Ann. Surg.*, 1946, 123: 516.

From their experience with spinal cord injuries, the authors found that the most frequent neurosurgical complications are the result of retained foreign bodies in close proximity to the spinal cord or peripheral nerve roots, intractable pain, and uncontrolled spinal reflexes.

Retained foreign bodies were found in 16 per cent of the cases. Their location within the spinal cord, or in or close to the cauda equina, the presence of intractable pain, or of a persistent draining sinus, determined the indications for operation. The removal of the foreign bodies, however, did not improve function but relieved the pain when pain was present, and the draining sinuses healed.

Pain is an old problem in paralyzed patients and contributes, by its persistency, to the patients' debility. The character of the pain differed from a root type to generalized burning, aching, or a pulling sensation, usually in an extremity but occasionally in the bladder and the rectum. Scar tissue was thought to be one of its causes, but was too extensive to be removed. The authors performed a spinal-thalamic cordotomy in 3 cases and obtained good

results. They noticed a marked improvement in the general nutrition of these patients after operation.

Uncontrolled spinal reflexes are present in a large percentage of paralyzed patients following spinal cord injuries and they present a very difficult therapeutic problem. They are described as simple flexion, extension, crossed extension, extensor thrust, reflex stepping, and mass reflex. No reflex characteristics typical of the level or degree of severity of the cord lesion could be found.

The authors point to the fact that many of these patients may have multiple and widespread lesions or discontinuous areas of hematomyelia causing confusion in the reflex pattern. From their observation, the extensor reflexes were generally found in anatomically incomplete lesions, and were frequently accompanied by clonus. They warn against performing destructive operations in such cases as they would permanently preclude the possibility of a spontaneous recovery of function. They advise a conservative course of treatment such as splinting, traction, and physiotherapy. They gave curare to some of their patients and found it useful only as an adjunct to other therapy.

For the patients in whom conservative measures did not help, more radical therapy was often helpful. Division of the anterior and posterior branches of the obturator nerves has relieved adductor spasms in paralyzing the principal adductor muscles, but because of the fibrotic changes which have occurred in the muscles and around the hip joints the authors recommend the application, for several months, of adduction splints immediately after the obturator nerve sections.

In patients with severe flexor and extensor spasms and a verified complete spinal cord lesion, anterior rhizotomy of the appropriate nerve roots became the procedure of choice. These patients may also require tenotomies for the release of fixed contractures around the joints. The authors report satisfactory results in 3 cases following anterior rhizotomy.

GEORGE PERRET, M.D.

Munro, D.: The Rehabilitation of Patients Totally Paralyzed Below the Waist, with Special Reference to Making Them Ambulatory and Capable of Earning Their Own Living. Urination. *N. England J. M.*, 1946, 234: 207.

The control of urination in paralyzed persons is a major social necessity and anything short of complete control becomes a source of mental misgivings and economic loss. To be unable to walk, or to walk well, is one thing, but to continually smell of urine and to be unable to spend a night away from home is another. This state of affairs may result from any serious injury or maldevelopment of the spinal cord unless the bladder is taken under immediate and rigorous control. This article is a very forcible discussion of the value of tidal drainage with its resultant "infallible 24 hour control of urination."

The cases studied included 125 selected from among 243 patients with injuries to the spinal cord

and, in addition, 24 in which tidal drainage was either not needed or not used. The treatment, if any, in these 24 cases studied for comparison is not mentioned. However, all but 1 of 101 patients were treated by tidal drainage and were taught to control their bladders so that they have "infallible 24 hour control of urination."

The treatment consists of the immediate placement in the bladder of a No. 16 or 18 Fr. soft rubber rectal tube, held in place with adhesive tape. For the last 6 years no urinary antiseptics have been administered by mouth but the bladder has been irrigated frequently with buffered citric acid solutions. The catheter is changed once a week and the fluid intake is kept at 4,500 c.c. per day. As soon as the bladder becomes active at a reflex level, training is begun so that in the end the patient need only pass urine every 3 hours or more and is able to go through the entire night without wetting the bed. Tidal drainage with an inbuilt apparatus for measuring the bladder pressure is necessary to satisfactorily carry out this program. No other method can accomplish these results.

Various complications are common with any method of controlling the bladder, but they are much less conspicuous in tidal drainage methods. Urethral complications may be avoided if nothing larger than a No. 16 or 18 Fr. catheter is used. Urinary infection is least with tidal drainage. These statements are supported by statistical tables.

Other methods of controlling the bladder are mentioned only to be condemned as inferior. Suprapubic drainage is to be used only under extraordinary conditions and should rarely, if ever, be necessary in civil practice. The methods are intermittent irrigation, penile clamp, suprapubic cystostomy, perineal urethrostomy, and rubber urinals. The reasons why these procedures are ineffectual are clearly and forcefully laid down.

ADRIEN VERBRUGGEN, M.D.

SYMPATHETIC NERVES

Nocito, F. J., and Nocito, G.: Surgery for the Relief of Pain. Anterolateral Chordotomy (*Cirugía del dolor. La cordotomía anterolateral*). *Prensa med. argent.*, 1946, 33: 285

The author reports 36 cases in which anterolateral chordotomy was performed with good results and he draws the following conclusions from his observations:

Two types of pain can be distinguished; peripheral or somatic, and visceral or splanchnic. Both types coexist only in the region of the external orifices, while in other parts of the body the sympathetic system does not participate in the production of somatic pain, and splanchnic pain is independent of the cerebrospinal system. Because of the synergism between the somatic, superficial pain and thermotactile functions, the stimuli responsible for painful sensation can be located and identified, while a deep pain can be located but the stimuli cannot be recognized. Factors responsible for the splanchnic

pain may be of a chemical, inflammatory, or ischemic nature. Polyradicular innervation is responsible for the fact that pain originating in the viscera cannot be located exactly.

The author discusses the anatomic paths of the conduction of pain and shows that anterolateral chordotomy is theoretically justified. He cites the following indications for the operation:

1. Locomotor ataxia, especially if one of the three conditions—visceral crises, so called topalgia or pains in the distal portion of the extremities, or pain caused by radiculitis of the cauda equina—is found to be present.

2. Cancer. Cachectic patients should not be operated on. Chordotomy is indicated particularly in the presence of a cancer of the female genital organs, prostatic gland, bladder, or pleural endothelioma, and in the presence of primary or secondary cancer of the spine. Suppression of pain without resort to the use of morphine facilitates proper nutrition and improves the general condition of the patient.

3. Other indications, such as ascending neuritis if a sympathetic gangliectomy had failed; plexitis or funiculitis due to a lesion of the spinal cord; painful amputation stump; Charcot's painful paraplegia; kraurosis vulvae; certain cases of painful fractures of the pelvis; chronic spondylitis; and deforming arthritis of the hip.

Only patients in a good general condition are suitable for the operation. Those weakened by chronic morphine poisoning should be built up with liver injections and blood transfusions. Hypotension requires attention because chordotomy favors syncope. Special attention should be paid to the condition of

the lungs, myocardium, and urinary tract before the operation is attempted.

Among the postoperative complications, retention of the urine is frequent and requires periodic catheterization. The normal vesical reflex is usually re-established on the fifth or sixth postoperative day. Trophic disturbances may be responsible for a disruption of the wound or the formation of decubital ulcers. Disruption of the wound occurs with relatively great frequency in patients with locomotor ataxia or hypoproteinemia. Many patients complain of radicular pains during the first few postoperative days. The pathogenesis of this complication is obscure. Possibly the pains are caused by an irritation of the posterior roots or an injury of the spinal cord during the operation. Motor disturbances also occur and may be ascribed to an irritation or a more serious injury to the pyramidal tract. A transitory or permanent paralysis may result.

In the authors' material only 1 case of transient paralysis was recorded.

The mortality in the authors' cases was 19.4 per cent.

As a rule, deep sensations are preserved after operation, but thermic sensations are abolished after a spinothalamic section.

In the authors' material failures were recorded in only 2 patients, or 5.5 per cent.

To combat visceral crises in tabetic patients, chordotomy is preferable to the interruption of intercostal nerves, operations on the solar plexus, posterior radicotomy, extirpation of the semilunar ganglion, or bilateral subdiaphragmatic vagotomy.

JOSEPH K. NARAT, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Martin, J. F., and Gulchard, A.: The Skeletogenous Tumors of the Mammary Gland (Les tumeurs squelettogènes du sein). *Lyon Chir.*, 1945, 40: 325.

Osteochondrogenous tumors of the breast are extremely rare, only 60 cases being on record in the entire literature. They are polymorphic, containing hyaline or calcified cartilage, osteoid or osseous tissue, either in rudimentary lamellas, or true bone with haversian canals and a medullary cavity. Myeloplaxes and osteoblasts are found either in the center of these bony structures or apart from them by themselves. These cartilaginous and bony elements are surrounded and held together by various kinds of connective tissue. According to the prevalence of one or the other of these tissues, the tumors are also called fibromas, myxomas, osteomas, or chondromas of the breast; however, they rarely show any systematization; but rather they are polymorphous connective tissue tumors, partly ossified or cartilaginous.

Thirty-four of the known 60 cases presented pure isolated skeletogenous tumors of the breast, 10 of these being benign osteochondromas and 24 (70%) being malignant osteochondrosarcomas. Twenty-six of the 60 cases presented mixed tumors of epithelial and mesodermal origin, fibromas or adenofibromas mixed with bony and cartilaginous elements. For the greatest part, these mixed neoplasms were malignant, giving the picture of skeletogenous epithelioma, others resembled carcinomas with zones of ossification.

Although 75 per cent of these tumors showed the histological traits of malignancy, the clinical course was comparatively benign. Their growth was very

Fig. 2. Ossified adenofibroma of the breast with the aspect of a partial liposarcoma. The metaplastic ossification of the adenofibroma is shown.

slow; they did not infiltrate into the surrounding tissue, and they may exist for many years without causing metastases. Only 20 per cent of the known cases showed metastases in other organs.

As to the histogenesis, the authors consider these tumors as cases of metaplasia from the epithelial to the connective and osteogenous tissue. In their mixture of epithelial and mesodermal elements, some of these neoplasms, the epitheliomas, remind one of the mixed tumors of the salivary glands. Extremely rare in the human being, these osteochon-

Fig. 1. Osteosarcoma of the breast.

Fig. 3. Skeletogenous epithelioma of the breast.

drogenous tumors of the mammary gland are frequent in animals, especially in the dog and cat.

The 60 cases included 9 cases observed by the authors, which were not published previously.

WERNER M. SOLMITZ, M.D.

Faugère, G. and Prat-Rousseau, C.: Resection of the Axillary Vein In the Radical Operation of Cancer of the Mammary Gland. (*Réssection de la veine axillaire au cours de l'opération radicale du cancer du sein*). *Bordeaux chir.*, 1942, 3: 131.

In cancer of the breast, the radical removal of all the lymph nodes in the axilla is a condition *sine qua non* to secure a lasting cure. One group of these lymph nodes, the subclavicular, is situated close to the axillary vein and, in cases of carcinoma, often adherent to it. For this reason, ligation and resection of the vein has been suggested by several writers. This procedure is advisable especially when carcinomatous nodes are found in the immediate vicinity of the vein. Histological examination has revealed invasion of carcinomatous cells in the adventitia of the vein.

The authors report 4 cases in which the axillary vein was resected because of adherent lymph nodes. Except for edema of the hand and arm during the first few months after the operation, no untoward sequelae were observed.

There is no doubt that the danger of metastases is reduced by the resection of the vein. However, 2 complications should be mentioned which may occur after the resection: pulmonary embolism and severe edema of the hand and arm. Neither of these complications was observed in the cases of the authors. The edema in these cases was not more severe than in many cases of the classical operation without resection. Apparently, the collateral circulation is sufficient to prevent severe edema, and it seems that the development of elephantiasis is caused by lymphangitis and following occlusion of the lymphatics by fibrosis, rather than by obstruction of the venous circulation.

Brown A.: Late Recurrences in the Skin following Radical Amputation of the Breast for Carcinoma. *Q. Bull. Northwest. M. School*, 1946, 20: 18.

Evidence that a tumor recurring in the skin after an operation for radical removal of the breast for carcinoma is a recurrence in the skin itself and not a generalized chest wall metastasis, falls into two categories.

1. The tumor should involve only the skin itself but may spread into a small amount of subcutaneous tissue. Any involvement of the deeper tissues, such as deep fascia or the tissues of the chest wall, throws doubt upon the origin in the skin as the skin involvement may be secondary to a deeper origin.

2. The tumor should be histologically not only a type of tumor that does not primarily occur in the skin but also a type that occurs in the breast and closely approximates the original tumor for which the primary operation was performed. However, in

the 3 cases presented it was histologically more malignant.

Little has been written concerning skin metastases and no differentiation has been made between true skin metastasis and that occurring in the deeper tissues of the chest wall. It is the authors' belief that the important part of the operation so far as skin recurrence is concerned is the careful undercutting of the skin to the limits of deep removal. It is not difficult to go too deeply into the subcutaneous tissue and leave a small particle of breast attached to the skin. If this is done it is not possible to state that the recurrence is in the skin since it may be from the small portion of breast left in the wound.

Three case reports are presented illustrating late occurrence of skin metastasis in patients who had undergone a radical resection of the breast for carcinoma. The skin metastasis occurred as follows: 10 years and 5 months, 1 year and 6 months, and 4 years and 4 months after the primary operation. The same technique was followed in each of the cases and an outline of the operative steps is reviewed.

The interesting points found in the review of the cases presented were:

1. None of the tumors was situated in the scar of the primary operation, which remained soft and flexible throughout its entire extent and was not at any point adherent to the chest wall. In each case the tumor was situated on the outer side of the scar, apparently at the site of a previous stitch hole, and did not spread from there toward the scar. In addition to the causes of local recurrence after radical mastectomy presented in the literature, such as (1) direct invasion from the adjacent primary tumor, (2) lymphatic emboli, (3) lymphatic permeation, and (4) emboli from the blood stream, one must also consider implantation of the tumor cells into the skin at the primary operation.

2. The time interval between the primary operation and the appearance of the skin involvement was quite long. The tumor, appearing in the skin itself and a small amount of subadjacent connective tissue was in all 3 cases a type of tumor that does not occur in the skin as a primary tumor.

3. In all cases the nodule in the skin was more cellular than the original growth which in each case contained large amounts of connective tissue and therefore presented the characteristics of scirrhous carcinoma.

TRACHEA, LUNGS, AND PLEURA

Burke, J., and Jacobs, T. T.: Penetrating Wounds of the Chest. *Ann. Surg.*, 1946, 123: 363.

A total of 402 patients with penetrating or perforating wounds of the chest were treated in a General Hospital during the campaign in Italy, from November, 1943 to September, 1944, and in Eastern France, from November, 1944 to February, 1945. It is the purpose of this paper to discuss the problems encountered, together with such conclusions as can be drawn from the observations. During the same

period of time an equally large number of patients with chest wall injuries, pulmonary contusions, and blast injuries of the lung had been treated. Many of these have had associated hemothorax, but have not been included in this study because the wounds had not penetrated the pleural cavity. Final end results cannot be discussed at this time for several reasons. The expression "returned to duty" cannot be accepted as an end result until it can be shown that such patient remained at full duty, or even limited duty.

The patients were received for the most part from Evacuation or Field hospitals. A few were admitted directly following accidents occurring in the vicinity; and another group was admitted from the Front without preliminary treatment in Forward hospitals. This occurred during the early days of the Anzio and Southern France invasions.

It was possible to follow with considerable interest the transition in Forward chest surgery with its increasing emphasis on conservatism. Certainly, patients are being received at present with pulmonary injuries and retained foreign bodies who would have been treated by formal thoracotomy at Forward installations a year ago. This conservatism is more than adequately justified by results. The authors were favorably impressed by the condition on arrival of patients who have had no more elaborate treatment than débridement and aspiration, or débridement and closure of sucking wounds. Many of these patients required no further formal intrapleural surgical treatment. Definitive chest surgery is best carried out at the nearest hospital, where an uninterrupted convalescence can be expected. The importance of minimal delay in travel is shown in detail in the discussion.

Hemothorax is by far the commonest single complication of penetrating wounds of the chest; it occurred in 78.5 per cent of the total number of cases studied.

Small, asymptomatic hemothoraces almost always will disappear in a short time if early ambulatory activity is encouraged. If a hemothorax is small and complicated by fever, dyspnea, or pain in the chest, aspiration is carried out for both diagnostic and therapeutic reasons. Many times pain can be relieved by the removal of a small amount of blood.

The large hemothorax must be aspirated early and frequently in order to obtain satisfactory results. The prime purpose of aspiration is to obliterate abnormal pleural space and allow the lung to re-expand. This is essential if the pulmonary dynamics are to be restored to normal.

The Baxter transfusion vacuum bottle and valve are used for aspiration. We have found the use of this apparatus to be a simple, air-tight and sterile method for the removal of chest fluid. It allows the removal of 600 c.c. of blood or air at one time, and the rate of removal can be easily adjusted by the use of the valve.

The removal of 600 c.c. at one time has been practiced. Aspiration of larger quantities results in

untoward symptoms such as cough, pain in the chest, and a feeling of faintness. When these symptoms appeared, aspiration was discontinued immediately.

The injection of air into the pleural space following thoracentesis was not used in any of the cases. The authors do not share the opinion that air replacement will prevent further bleeding from the expanded lung. That bleeding recurs after aspiration is conjecture and is not validated by proof. The opposite has been found to be true by studying the hematocrit, hemoglobin, and plasma protein of hemothorax fluid. A sample of the aspirated fluid was studied by the Van Slyke copper sulfate method after each aspiration and it was found that in no instance was there evidence of increased bleeding. In fact, in all patients aspirated more than once, there was a definite progressive decrease in the hematocrit and hemoglobin readings of the fluid.

Clotted hemothorax has been the subject of much controversy among thoracic surgeons in World War II. A distinction must be made between an inspirable hemothorax and a clotted hemothorax. The clotted hemothorax obviously is not aspirable, but it does not necessarily follow that the inspirable hemothorax is clotted. The traumatized chest wall and lungs are prone to form many bands and points of adherence which may make aspiration difficult or even impossible. Uninfected inspirable hemothorax is treated conservatively, by repeated attempts at aspiration, blood replacement, early ambulatory activity, and breathing exercises. If at the end of 3 weeks there was no evidence of expansion of the lung and disappearance of the blood, a thoracotomy and decortication were done.

The management of intrathoracic foreign bodies, abdominothoracic injuries, contusion of the lung, lung abscess, empyema, and wounds of the pericardium and heart is reported in detail, special emphasis being placed on the general care of the patient.

A low incidence of empyema, clotted hemothorax, operative procedures necessary, and the low mortality rate of 0.9 per cent are shown.

It is suggested that early, frequent aspiration, adequate blood replacement, and early ambulation are extremely important in the reduction of the incidence of complications.

It is further suggested that definitive treatment of penetrating chest wounds may be carried out most satisfactorily in the Forward General Hospitals.

JOHN E. KIRKPATRICK, M.D.

Harper, E. H. G., and Tait, G. B.: Pulmonary Edema in Chest Wounds. *Lancet*, Lond., 1946, 1: 533.

Pulmonary edema is the most serious complication in large lacerating wounds of the lung.

In the authors' cases, in spite of treatment with oxygen, atropine sulfate, and hypertonic plasma, all but 1 were fatal.

The one surviving patient, after receiving the usual treatment, finally underwent venesection and within an hour improved dramatically.

The mechanism of the production of pulmonary edema is discussed.

A warning is given against the use of intravenous infusions in severe chest injuries, as they tend to produce pulmonary edema. JOHN J. MALONEY, M.D.

Mattel, C., Recorder, M., Metras, H., and Barbe, A.: An Attempt to Treat Pulmonary Suppurations with Endobronchial Installations of Penicillin (Essai de traitement des suppurations pulmonaires par des installations endobronchiques de pénicilline). *Presse méd.*, 1946, 54: 185.

As the systemic treatment with penicillin in cases of severe pulmonary abscess did not give satisfactory results, topical treatment was tried. Under control of the fluoroscope, rubber tubes were introduced into the abscess via the trachea and bronchi, and penicillin was applied locally. The results were far superior to those following systemic therapy. Fifty thousand units dissolved in 20 c.c. of serum were instilled twice weekly. Of a series of 12 cases of pulmonary abscess, 7 were cured completely, clinically and as shown by the x-ray findings. Four cases were cured clinically but showed some degree of stiltations necessary for complete success varied between 4 and 10. Nine of the patients had been treated with intramuscular injections of penicillin before they were given the installations.

WERNER M. SOLMITS, M.D.

Brock, R. C.: Studies in Lung Abscess. *Guy's Hosp. Rep.*, Lond., 1945, 94: 115.

The present article represents the first of a series of essays on lung abscess, based on 12 years' experience. The author discusses staphylococcal lung abscess. In the introduction he discusses the desirability of determining the type of lung abscess in each case of the disease.

The primary clinical picture is of a severe and overwhelming general infection referred to as "staphylococcal fever" frequently having the picture of a septicemia. It may be of sudden onset, beginning with symptoms suggesting pneumonia and pleurisy, and proceeding to the expectoration of sputum to suggest abscess formation. Involvement is frequently bilateral. Unilateral involvement is often massive and confluent.

The condition cannot be diagnosed by any one feature alone, but a combination of features is often sufficient to suggest the type of disease. Radiological examination may be strongly suggestive by the bilateral or multilobar involvement, and may present abscess cavities which often reach a large size and typically contain only a trace of fluid, or are completely empty. This is referred to as a "soap bubble" type of appearance. Very large tension cavities, or the onset of spontaneous or tension pneumothorax, especially in an infant, are very suggestive.

Proof, of course, depends on demonstration of the staphylococcus from the sputum, and/or the blood

stream, or in a secondary focus. The staphylococci may be present in pure culture, although mixed cultures are not uncommon.

Staphylococcal abscess of the lung was not seen as a sequel to aspiration of infective material from bad teeth, tonsils, or following operation on the upper respiratory passages.

"The absence of a predisposing cause for bronchial embolism, a very toxic or septicemic patient and large distention abscess or abscesses in the lung without much retained secretion furnished the prima facie evidence for a diagnosis of a staphylococcal illness."

The author has treated 30 cases, with a mortality of 20 per cent. The cause of death was cerebral abscess in 2 cases, and pyemia or septicemia in the remaining 4 cases. Of the 24 patients that survived, 11 have no indication of permanent lung damage, whereas 12 have symptoms. Of this latter 12, 6 had bad "chest trouble" previously. Empyema occurred in 10 of the 30 cases. The fact that pulmonary disease may well be active under the empyema in staphylococcal abscess is pointed out.

A rather detailed description of the clinical appearance and course of these patients is given, supported by 8 rather detailed case reports and 15 roentgenographic reproductions illustrating the various types of findings in this disease.

HIRSH T. LANGSTON, M.D.

Adams, R.: Primary Lung Tumors. *J. Am. Med. Ass.*, 1946, 130: 547.

A diagnosis of primary carcinoma of the lung was established microscopically in 157 consecutive cases at the Lahey Clinic in a 15 year period ending in December, 1944. The authors point out that most often early diagnosis is not made because the patient fails to seek medical advice or does not consider the complaint seriously enough to seek proper diagnosis. The symptomatology of cancer of the lung is largely explained by bronchial encroachment with varying degrees of obstruction or ulceration in that structure. The most common symptoms are: cough (93%); pain or chest discomfort (54%); sputum of varying types (53%); hemoptyses (44%); and wheeze caused by incomplete obstruction of the bronchus (14%). A sixth symptom not so frequently found was dyspnea, which occurred in 17%. The diagnostic procedures including sputum examination, bronchoscopy, roentgenography, and study of the pleural effusions and of biopsies were discussed. The article is summarized by the following statements:

Over a 15 year period from 1930 to 1944, with 164 consecutive cases of microscopically proved primary lung tumors, 7 nonmalignant tumors were observed. One was a myxochondroma and 6 were bronchial adenomas. There was no hospital mortality, and the 7 patients are alive and well at the present time.

There were 157 cases of carcinoma of the lung, and 49 patients (31.4 per cent) were submitted to surgical resection. Among the resected group, there were 8 hospital deaths (16.3 per cent). Twenty-three deaths

(46.9%) occurred subsequently because of recurrence of the disease. Four patients (8.1%) are living with evidence of recurrence. Fourteen patients (28.5% of 49 and 8.0% of 157) are alive and well at the present time with a chance for five year survival. Technical procedures have reduced the mortality to 3.3 per cent in the last 4 years in consecutive resections.

Brown, B., Orr, E. M., Meads, M., and Finland, M.: Penicillin Treatment of Empyema: Report of 24 Cases and Review of the Literature. *Ann. Int. M.*, 1946, 24: 343.

It is generally believed that the sulfonamides will not cure empyema once frank pus develops. When properly used early in treating pneumonia, they will reduce the incidence of empyema, they cure an early empyema without open drainage. Penicillin should be more useful than sulfonamides in treating empyema, since the organisms frequently associated with empyema, namely pneumococci, hemolytic streptococci, anaerobic streptococci, phyllococci, fusospirochaetes, and others are more susceptible to penicillin. Penicillin diffuses from the blood stream into the pleural cavity and can be found in pleural fluids in concentrations which are somewhat lower than those of the blood. In accordance with the dosage, size of the cavity, and thickness of the wall, penicillin injected into the pleural cavity diffuses out into the blood stream slowly. Appreciable amounts are present in the pleural space from 24 to 72 hours after the injection. Penicillin's action is not inhibited by pus, tissue autolysates, or para-aminobenzoic acid. Its activity may be destroyed by certain micro-organisms or their products. Since treatment is often prolonged, a less toxic drug like penicillin is preferred to the sulfonamides.

A series of 24 cases treated with penicillin at the Boston City Hospital between March, 1944 and September, 1945, are reviewed. The ages of these patients varied from 4 to 72 years and three-fourths of them were 40 years or older. All but 4 were males. The empyemas followed primary pneumonia in 15 cases. In 2 cases they followed postoperative pneumonia; in 1 case the empyema was the result of atelectasis following a blow to the chest, in 1 it was part of a general sepsis, in 1 it was a chronic empyema of 20 years' duration, and in 4 cases the condition was a putrid empyema associated with pulmonary suppuration.

The pneumococcus was the most common organism, occurring in 14 cases. The alpha hemolytic streptococcus, anaerobic streptococcus, microaerophilic streptococcus, staphylococcus aureus, or mixed infections were found in the other cases. All but 3 patients received sulfonamides before penicillin was started, with no curative effect. Intramuscular doses of penicillin averaging 120,000 U. daily were given to 22 of the patients for an average of 15 days. Intrapleural doses of penicillin

of from 5,000 to 200,000 U. were used with an average of 6 institutions.

The organisms were tested for sensitivity to penicillin. After a single intramuscular dose of 40,000 U. the concentration in the pleural fluid from 1 to 2 1/2 hours later ranged from 0.03 to 0.22 U. per cubic centimeter. The corresponding serum concentrations were from two to eight times as high. Concentrations as high as 40 U. per cubic centimeter were found in pleural fluid 24 hours after local institution of from 30,000 to 60,000 U. Serum concentrations similar to those obtainable after the usual intramuscular doses were maintained for 24 hours after intrapleural doses of from 100,000 to 200,000 U.

Most of the patients improved markedly within 24 hours after penicillin treatment was started. 24 of the pleural fluid became sterile and remained so after a single intrapleural dose in 6 cases, after two injections in 5 cases, and after the sixth injection in 1 case. Frequently, organisms persisted in smears for several days after the cultures became sterile. Positive blood cultures were obtained at the time of admission in 7 cases. Penicillin seemed to decrease the volume of fluid that could be aspirated. For the foul odor of putrid empyema to disappear, and the patients became much better operative risks.

Of the 9 patients treated with penicillin and aspirations alone, 6 were cured (5 with pneumococcal and 1 with staphylococcal empyema). Two patients in the nonoperative group died of obscure causes. Operative drainage through a rib resection was carried out in 15 patients. Twelve were cured and 3 died; in 1 patient with a rib resection the condition became chronic and a draining sinus was present 7 months after operation. Of the 4 patients with putrid empyema, 3 were cured, and 1 patient with developed chronic empyema and a draining sinus. The nonoperative cases averaged 47 days in the hospital, while the operative group averaged 86 days.

The authors analyzed the important features of 261 cases treated with penicillin collected from the literature, including their own 24 cases. All of these developed empyema on the basis of an antecedent pulmonary infection. Complete cures without resort to open drainage were obtained in 55.4 per cent of the group.

Rib resections were carried out in 40 per cent of the series. Seven nonoperative cases were cured with intramuscular injections of penicillin alone. The final results with respect to mortality and the percentage of cures or of cases that became chronic were essentially the same in the operative and nonoperative cases.

The most frequent organisms involved were the pneumococcus, beta hemolytic streptococcus, and staphylococcus, in that order. These are more favorably affected by penicillin than anaerobic streptococci or mixed infections. Of the cases of mixed infections only about one-fifth were cured without operation. The greatest percentage of deaths and chronic empyemas occurred in this mixed infection

group. The penicillin in these cases was given intrapleurally, intramuscularly, or both ways. There does not seem to be any correlation between the size of individual intrapleural doses, their number, or frequency. The most common intrapleural dose in use now is from 50,000 to 100,000 U. In two-thirds of the cases the penicillin treatment was given over a period of less than 3 weeks. In more than one-half of the 56 cases in which the number of injections required to sterilize the pleural fluid was stated, one or two injections were made. In 22 cases it was not sterilized at all. Systemic therapy is probably not essential in most cases if intrapleural injections of 100,000 U. or more are given at 24 to 48 hour intervals.

The susceptibility of organisms to penicillin, the duration of the illness, the thickness of the pleura, the presence of thick pus, fibrin clots, loculations, bronchopleural fistulas, or a draining sinus all play an important part in the sterilization and obliteration of empyema cavities. They may require surgical interference. Intramuscular administration of penicillin is particularly useful if the underlying pulmonary lesion is still active.

The greatest objection to the nonsurgical treatment of empyema has been the fear that the patient would be left with a thickened and immobile pleura, and that pulmonary function would be reduced. Impairment of function, pleural thickening, and other difficulties are not necessarily less, and may even be greater, following operation than in the cases in which operation can be avoided. Operations also leave ugly scars and considerable deformity.

The proportion of cures without operation has varied widely in different reports. Some authors have operated on practically all of their cases and concluded that penicillin has altered the treatment of empyema only slightly or not at all. Others obtained cures in almost all of their cases treated with penicillin and aspirations alone, and maintain that the need for rib resection has been markedly reduced. On the basis of accumulated experience, it seems evident that at present more than one-half of all cases of empyema can be cured by repeated aspirations and local instillations of penicillin into the pleural cavity.

The use of sulfonamides in treating pneumonia has not materially affected the incidence of empyema. It is expected that penicillin may do this. The indications for rib resection and the optimum time when it should be done when penicillin has been given remain to be worked out and will vary in different patients. In general, as long as the patient continues to improve, the cultures remain sterile, and the fluid diminishes in quantity, it is safe to continue with conservative therapy. Most patients who are eventually cured show marked improvement within the first 2 weeks.

It is not desired to leave the impression that rib resection and other forms of surgical drainage have been entirely replaced by penicillin therapy and simple aspirations. These operations will still be

necessary in many cases. However, now more empyemas than ever can be cured without open surgical drainage. This results in a shorter illness and a shorter period of disability.

ROBERT R. BIGELOW, M.D.

Platt, A. D.: Primary Mesothelioma (Endothelioma) of the Pleura. *Am. J. Roentg.*, 1946, 55, 173.

In a brief review of the literature on primary mesothelioma of the pleura, an incidence of 1.1 cases per thousand autopsies was reported by Saccone and Coblenz, with greatest frequency between the ages of 40 and 60 years, and, according to Birnbaum, a ratio of males to females of 2 to 1. He notes that the clinical findings are often reported to simulate those of a chronic inflammatory process, but that chest pain is early and persistent, and is accompanied by a dry cough, with rapid loss of energy and some loss of weight. Roentgen examination early in the disease has been found of little help in identifying the nature of the lesion, for it may show only a slight pleural effusion at the base of the involved lung. Later the effusion becomes massive and obscures the entire lung field, and only occasionally are tumor nodules visualized after a thoracentesis. Several authors have emphasized that when thoracentesis is attempted in these cases, the needle often seems to strike against firmly resistant tissue. The pleural fluid may or may not be bloody, and may or may not reveal malignant cells.

The author reports a case which, while showing the features outlined, demonstrates the difficulties encountered clinically in diagnosing pleural mesothelioma. The patient was a woman of 33 when first seen (in 1937) because of constant pain in the left lower thorax for several months, accompanied by a nonproductive cough, intermittent low grade fever, and fatigue. Physical examination disclosed tenderness over the left eighth rib but no abnormality of heart or breath sounds; the roentgenogram showed only rather minimal left pleural effusion. When she returned 15 months later, complaining of increased severity of the symptoms, dyspnea, and weight loss, there was both physical and roentgen evidence of increase in the left pleural effusion, fracture of the left eighth rib, and apparent general enlargement of the cardiac silhouette. Cardiac disease was suspected, but the electrocardiogram was normal except for sinus tachycardia. Two months later (March, 1939) a dense nonpulsating mass was seen close to the left cardiac border, and the diagnosis was now thought to be bronchogenic carcinoma. Films taken in May, 1939 because of pelvic pain showed osteolytic metastases in the right innominate bone. Palliative irradiation to the thorax and the pelvis gave only transient relief of pain. During repeated thoracenteses it was noted that there was always difficulty in forcing the aspiration needle into the pleural space; no malignant cells were found in the aspirate. The patient became increasingly emaciated and died in October, 1939, over 2 years after the first onset of chest pain.

hemorrhage during the course of the cholecystectomy. Here again, direct ligation of the cystic artery and duct will avoid this complication. If severe hemorrhage does result from a cystic artery that slips through a clamp, rather than blindly clamp into the region of the artery one can control the hemorrhage by digital compression of the hepatic artery in its course anterior to the foramen Winslow and then seek the offending vessel which there is severe inflammation with much edema and inflammatory change in the tissues of the cystic artery. In such cases the hemostatic clamp can be left on, the incision can be closed about the clamp and the clamp can be loosened and removed in 4 or 5 days. Cholecystostomy may be the procedure of choice in these cases, cholecystectomy being performed at a later date.

The presence of anomalies in the biliary system as well as in the corresponding vessels makes the direct ligation of the cystic duct and artery imperative. Eisendrath in his classic study showed the frequency of abnormal relations. He found that 17 per cent of cystic ducts parallel the course of the common duct, occasionally to within 1 centimeter about the ampulla. The cystic duct spiraled anterior, posterior or parallel to the cystic duct. The cystic artery may arise to the right or left or behind the common duct and may pass in front of it or behind it. The cystic artery is double in 12 per cent of the cases. We believe that the extensive obliteration of the duct system, which in many cases extended into the intrahepatic ducts, can be attributed to chronic inflammation of the epithelium of the ducts. At least 12 per cent of the patients can be classified on such a basis. In one case known surgical trauma was followed by such an extensive obliteration of the bile ducts. This no doubt may explain the even though they also presented external biliary fistula. In consideration of the possibility of this lesion resulting from rigorous curettage of the mucosa of the bile duct in

performance of choledochotomy, we feel that particular care should be exercised in exploration of the common duct and that exploration of the common duct should not be carried out unless there exist definite indications for it. The chronic obliterative cholangitis which these patients present is due to a slowly progressive chronic inflammation that destroys the normal epithelium and leaves a scarred, contracted, nearly obliterated common duct.

We wish to emphasize that this group of patients do tolerate operation well and we believe that this fact should encourage surgical exploration in an attempt to re-establish the continuity of the biliary system, even in those cases in which the risk is considered to be grave. One is greatly impressed with this ability to undergo extensive operations, for these 188 patients underwent a total of 496 operations with only a 12 per cent mortality rate for the 188 procedures which we are studying. Two hundred and fifty-seven of these operations had been performed elsewhere. The ability of the liver to maintain a satisfactory function after years of constant injury is manifested by the 4 patients who suffered from symptoms of cholangitis for 10 to 12 years but were still alive at the time of the latest report.

Nearly a half of the patients who were well, 2 to 12 years after their reconstructive operation, had suffered from symptoms of biliary dysfunction which had subsided entirely. We would stress this fact in any evaluation of patients who return after a reconstructive operation for further management. Although many of these patients had chills, fever, jaundice and an enlarged tender liver at one time, they later became free from symptoms. One such patient after choledochoduodenostomy had suffered from symptoms of cholangitis for 2 years but had been entirely free of symptoms for 7 years at the time of the latest report. Apparently cholangitis is the factor present in these cases rather than a mechanical obstruction. Patients who have cholangitis improve when treated with sulfonamide drugs and when simultaneously the rate of flow of bile is increased by use of bile salts and increased ingestion of fluids. One can be aided in de-

At autopsy the left visceral and parietal pleurae were found diffusely thickened, studded with nodules and adherent to each other and to the pericardium, except where separated by loculated bloody fluid. The left lung was atelectatic and contained scattered discrete tumor nodules, as did the right lung. There was a right serofibrinous effusion, and the right visceral pleural surfaces were tumor-studded but not otherwise thickened. No evidence of a primary bronchial tumor site was found. The tumor tissue had invaded the pericardium diffusely and there was an accompanying pericardial effusion. The left eighth rib was the site of a small osteoclastic metastasis. No abdominal visceral metastases were found. The microscopic sections showed the left pleura tremendously thickened by tubules, columns, nests, and sheets of large anaplastic pleomorphic nuclei, some in mitosis, embedded in fibrous stroma, and filling countless lymph spaces.

LILIAN DONALDSON, M.D.

MISCELLANEOUS

Nicholson, W. F.: Penetrating Wounds of the Chest. *Brit. J. Surg.*, 1946, 33: 357.

The author presents a survey of 1,639 penetrating chest wounds seen in the Middle East and Central Mediterranean Forces. The patients were received immediately after being wounded up to 3 or 4 weeks after being wounded, according to the tactical situation. The overall mortality was 4.27 per cent.

On x-ray, wounds of the lung may present the missile track, although most often a pulmonary hematoma is the pathological picture. Such intrapulmonary hemorrhage was believed important in producing a "wet lung." Most of these resolve spontaneously. "A few pass on to pneumonia; fewer still to an abscess." Atelectasis was common, particularly in the presence of hemothorax. Bronchoscopy was infrequently used.

Pneumothorax alone is infrequent although it is present, in some degree, in all penetrating wounds. Tension pneumothorax was seen in 1.5 per cent of all cases. Of 24 patients, 10 died later of sepsis.

Hemothorax occurred in 1,027 cases, or 62.6 per cent of the series. Of these, 718 remained uninfected and fluid; 217 were infected and fluid; 92 were clotted. Seventy-five per cent of the last group were infected. Empyemas occurred in 22.3 per cent. There were 8 cases in which further bleeding into the pleura occurred 24 hours after wounding.

There were 6r clotted or loculated hemothoraces on the right, and 32 on the left. Evacuation of the clot and decortication were employed in such cases.

Five factors which favor the development of a chronic empyema are listed: (1) the wound of the lung may produce a permanent scar with inability of the affected lung to expand; (2) prevalence of staphylococcus aureus infection, an organism which produces no fibrinolysin; (3) retained foreign body; (4) bronchopleural fistula; (5) fibrin deposit on the visceral pleura, which is tough and unyielding.

There were 164 thoracoabdominal wounds, 10r on the right and 63 on the left. Conservatism in the management of liver injuries was more common than operation, and when the latter was carried out the abdominal root seemed to predominate. Subphrenic abscesses were seen in the proportion of 13 on the right and 7 on the left. Six cases of bile pleuritis became infected. There were 2 cases of bronchobiliary fistula. The mortality at the Base Hospital in thoracoabdominal wounds was 22 per cent.

Intrapleural foreign bodies were seen in 39 cases with empyema in 26. Intrapulmonary foreign bodies, 1 by 2 centimeters in size, were removed, as well as the intrapleural ones. Smaller foreign bodies were removed after resolution of the pulmonary hematoma. Eight cases of lung abscess due to a retained foreign body were seen.

Foreign bodies in or near the pericardium were removed, particularly if there was evidence of "recurrent pericarditis from irritation by a foreign body."

Foreign bodies in a vertebral body, particularly in the presence of infection, constitute a serious problem.

A program of rehabilitation is stressed. Breathing exercises are important, but caution against instituting them during active phases of infection is given.

Eight case reports, including good illustrative roentgenograms, are used to document the discussion.

HIRAM T. LANGSTON, M.D.

Rose, T. F., and Newson, A.: Treatment of Gunshot Wounds of the Chest in the Field Aided by Penicillin Therapy. *Med. J. Australia*, 1946, 1: 290.

The authors report 32 cases of gunshot wounds of the chest with intrapleural involvement. The treatment was based on adequate resuscitation, early excision and suture of the wounds, early and repeated aspiration of hemothoraces, and early thoracotomy for fibrinohemothorax and pleural infection.

Penicillin therapy, both intrapleural and intramuscular, was used as an adjuvant in all cases.

SAMUEL KAHN, M.D.

Santy, P., Bérard, M., and Mallet, P.: Gas Embolism in Thoracic Surgery (Les embolies gazeuses en chirurgie thoracique). *Lyon chir.*, 1945, 40: 68r.

The authors report 10 observations of a complication which is the most difficult to avoid in thoracic surgery, namely, gas embolism. The authors are dealing only with so-called arterial gas emboli which pass the left side of the heart and show a tendency to enter one of the branches of the aorta in an ascending direction. In view of the usual position of the patient the embolus most frequently enters the carotid arteries. The most important signs of gas embolism are syncope, epileptiform crises, and hemiplegia. If syncope does not lead to a fatal

INTERNATIONAL ABSTRACTS OF SURGERY

outcome it is followed by a more or less prolonged coma. Epileptiform crises are either generalized or of the Jacksonian type and, as a rule, are not accompanied by a loss of consciousness. Hemiplegia or monoplegia is relatively rare, may or may not involve the face, and is sometimes accompanied by aphasia and conjugated deviation of the head and eyes. Pallor, profuse perspiration, anxiety, vomiting, and dilatation of the pupils complete the clinical picture. Respiration is slow and labored, frequently stertorous, and cyanosis is frequently observed. The authors stress the great frequency of a sudden malaise preceding the appearance of objective signs.

There are other important symptoms such as amaurosis, and cardiovascular and cutaneomucous signs. Amaurosis is probably caused by an embolism of the retinal arteries. Extrasystolic arrhythmia and, strangely enough, arterial hypertension are constant signs, although of short duration. The classical windmill murmur signifies the "barbotage" of air within the heart. Erythematous patches on the face, neck, upper extremities, trunk, and the mucous membranes of the tongue and cheeks, surrounded by pale zones, are bizarre phenomena. Such cutaneous lesions may change their shape and location and may reappear in old places, the changes being due to the movements of the peripheral emboli and topographic modifications of the stasis of the blood.

Of 10 cases of gas embolism observed by the authors 5 ended fatally.

Gas embolism following thoracoplastic operations seems to be a rarity.

A too vigorous lavage of the pleural cavity or introduction of a drain may produce gas embolism in some cases.

The authors have noticed repeatedly that embolism originates during the inspiratory phase of respiration, which produces a dilatation of the alveoli and pulmonary veins.

Insufflation, puncture, or exploration of the pleural cavity should not be undertaken until one is sure that the tip of the needle is within the pleural cavity. No air should be injected under high pressure, especially if the existence of a circumscribed cavity is suspected. If symptoms of gas embolism appear, the patient's head should be lowered to prevent the entrance of the air into the carotid arteries. Before a resection of a lobe or its portions, the pulmonary parenchyma should be clamped. No brisk traction should be applied in order to avoid an injury of the lung tissue. Pneumotomy should be performed only with an electric knife which produces a progressive coagulation of the tissue. Finally, the authors advise covering the operative field with large pads soaked in saline solution so that a protective liquid layer is created.

As to the curative treatment, the patient's head should be lowered, the wound should be covered with wet compresses, and vasodilating drugs such as papaverine or acetylcholine should be employed. Cyanosis should be combated with oxygen inhalations, and artificial respiration is indicated in syncope. The authors highly recommend intravenous injections of from 10 to 15 c.c. of novocain.

JOSEPH K. NARAT, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Stajano, C.: The Supposed Difference in the Defensive Power of the Peritoneum in Distinct Sectors of the Abdomen (La pretendida diferencia defensiva del peritoneo en los distintos sectores del abdomen). *Rev. mex. cir.*, 1945, 13: 102.

In this polished disquisition on the philosophy of error, the distinguished Uruguayan professor of clinical surgery attempts to limit himself to that particular sophistry, prevalent in the medical profession and particularly among surgeons, which teaches that there is a difference in the defensive reaction between the peritoneal surfaces of the lower and upper sectors of the abdominal cavity. He does not try to prove by positive evidence that Ranvier was wrong in asserting that there were distinctive differences between the lymphatic arrangement of the lower and upper abdominal regions, or that Clark—also about the turn of the century—was practically in error in recommending his declivitous posture for the patient, viz., almost a Trendelenburg posture, to favor the reabsorption of the products of peritoneal effusion or hemorrhage. Nor does he say that Fowler's position for surgical patients has not been of any practical value. He merely states that today there is no basis for the profession's being guided by these conceptions.

These erroneous ideas arose during the period when morphology rather than physiology dominated surgical thought, when judgments based on anatomical structure were the mode in surgery, and subsequent investigators piled error upon error in trying to prove that this theory was true, instead of trying to establish its authenticity. For instance, it was pointed out that the pelvic peritoneum resists infection much better than the peritoneum in the upper abdominal regions. However, in recent years it has been shown that there is no basis for such an assumption. The apparent difference was due to the prevalence of gonococcus infections in the lower abdominal regions, and it is known that the gonococcus is by nature a fragile organism and is incapable in itself of much aggression within the body. It is the exotoxins and particularly the endotoxins of the gonococcus which produce the congestive and exudative manifestations which look so virulent to us. On the other hand, the streptococcal involvements of the lower abdominal regions, such as the puerperal abscesses of the tubes and ovaries, are just as virulent and deadly as streptococcal infections anywhere else in the body.

In the upper abdominal region the grave prognosis of infections of the biliary tract was assumed to be due to the spongeliike absorptive capacity of the peritoneal surfaces about the diaphragm, but no notice was taken of the fact that infradiaphragmatic abscesses allowed of about as much tempo-

rizing and were almost as easy to cure as the corresponding involvements of the pelvis. It is now shown that the deaths from biliary infections are due to injury to the parenchyma of the liver rather than to special conditions of defense reactivity and absorption of the peritoneum.

The surgeons of the early nineteen hundreds were timidly attempting gastroenterostomies and gastrotomies for cancer of the esophagus and blaming their failures on the special conditions to be encountered in the peritoneum of the upper abdominal cavity, rather than on the true causes, such as failure of the suture line, occlusion of the neostomies, intestinal loop herniations, high intestinal occlusions, and hemorrhage into cavities or into the peritoneal cavity itself. All such accidents were ascribable to the operator himself or to his preparation of the patient. Today the simple closure of perforated gastric and duodenal ulcer and the vast excisions of the upper alimentary tract, with or without drainage, discredit any such theory as a special fragility of the upper peritoneal cavity.

All in all it seems that the peritoneum possesses an extraordinary capacity for defense throughout all sectors of the abdominal cavity, and that it is the particular biologic qualities of the individual invading organism, and its particular intensity and modality of aggression which determine the differing gravity of the processes within the general abdominal cavity. Fowler's position is of value because it transports the products of infection to regions of the body, such as the cul-de-sac of Douglas in the woman, where drainage may be more easily and effectively done.

JOHN W. BRENNAN, M.D.

Figari, A.: The Causes of Acute Peritonitis Observed at the Autopsy Table (Le cause delle peritoniti acute osservate al tavolo anatomico). *Policlin.*, sez. prat., 1946, 53: 61.

The author presents a statistical analysis of cases of acute peritonitis seen at postmortem examinations at the Policlinico, Umberto I, between 1937 and 1942.

Deaths from acute peritonitis were found to account for 5.7 per cent of the total autopsy material during the period under observation; appendicitis and postoperative peritonitis were the etiologic factors in 22.3 per cent and 18.5 per cent, respectively. In 13.7 per cent of the cases the peritonitis was attributed to perforated gastric and duodenal ulcers, while in the remaining 46 per cent it was due to strangulated hernias, gynecological lesions, perforations of the gastrointestinal tract due to neoplasms, volvuli, perforated typhoid ulcers, suppurative processes, and unclassified ulcers of the small and large intestine.

The deaths from complications of appendicitis were found to decline from 25.2 per cent in 1937 to

19.6 per cent in 1942, while perforations from peptic ulcers were seen to rise from 12.6 per cent to 17.5 per cent. Postoperative peritonitis maintained a constant rate of 20.7 per cent until 1942 when it fell to 7.2 per cent. EDITH FARNSWORTH, M.D.

Mosto, D., and Pastorini, R.: Pseudomyxoma of the Peritoneum (Pseudo mixoma peritoneal). *Am. Atenco Inst. maternidad*, 1945, p. 65.

The 5 patients observed by the authors were from 25 to 60 years of age (2 males and 3 females). In 4 appendectomy was performed. One patient had undergone an appendectomy and presented a fistula discharging gelatinous material. In 4 of these cases the diagnosis was appendicitis (in 1 instance with a perforated appendix). The remaining patient exhibited a chronic follicular appendicitis with peri-appendicitis and vascularitis, and the terminal portion of the small intestine displayed a dense crop of milium granulations over an area of 10 sq. cm., which proved on histologic examination to consist of vascularized, myxomatous granulations containing glandular structures of appendicular type.

In 3 of these patients the picture was that of a secondary specific irritation of the peritoneum by the mucous deposits, and in the others the picture resembled that of implants of glandular tissue from the appendix to the peritoneal surfaces.

The authors believe that their material supports the statements of other authors (von Rubnitz and Hermann: *Archives of Pathology*, 1943, 36: 297), that there are 2 forms of pseudomyxoma of the peritoneum of appendical origin—one a benign type which will often disappear when the appendix itself is removed, and the other a form with mucosal implants, which are apt to undergo malignant degeneration, especially if the process spreads extensively over the peritoneal cavity. This last form requires postoperative irradiation, and in spite of this may terminate fatally. JOHN W. BRENNAN, M.D.

Thompson, G. C. V., and Chambers, C. H.: Chylangioma of the Mesentery, with Report of a Case, and a Brief Discussion of Mesenteric Cysts. *Med. J. Australia*, 1946, 1: 210.

A chylangioma of the mesentery has been defined by Ewing as a cavernous lymphangioma containing milky fluid, which arises from congenital or acquired obstruction of the lacteal vessels. Chylangioma constitutes one type of true mesenteric cyst, in that it conforms to the definition of a mesenteric cyst given by Higgins and Lloyd, who held that mesenteric cysts were cysts which occurred in or near the mesentery, which were not malignant, dermoid, or parasitic, and which did not arise from any normally placed retroperitoneal organ.

Chylangiomas are considered benign tumors whose embryonic origin is stressed by many authors. They occur most frequently at the primitive centers of origin of lymph tissue in the embryo.

Macroscopically, chylangiomas are well differentiated from surrounding tissues, having a capsule

which varies with the size of the cysts, with their situation, and according to whether they are pedunculated or sessile, or whether they project between the layers of the mesentery. The tumor may be a single cyst or a multilocular cyst with cystic spaces of varying size; it may be entirely cystic or partly fleshy.

The authors report a case of chylangioma of the mesentery at the duodenojejunal junction. The cyst had the features of a true tumor of the lacteals. The confused classification of mesenteric cysts was discussed, and an attempt was made to describe common types of mesenteric cysts. The clinical signs, symptoms, diagnosis, and treatment of mesenteric cysts were briefly stated. CHARLES BARON, M.D.

GASTROINTESTINAL TRACT

Ricketts, W. E., and Pollard, H. M.: A Roentgenological and Gastroscopic Study of Gastric Disease. *Gastroenterology*, 1946, 6: 1.

The purpose of this report was to present an analysis of a series of 1,297 patients with gastric disease who were studied both by means of x-rays and gastroscopy. In general, it was agreed that the shape, contour, motor function, and gross lesions are seen better by means of the x-rays, while mucosal changes and small lesions are seen better with the gastroscope.

Duodenal lesions obviously not detectable by gastroscopy were excluded from the analysis. Cases with gastroscopic and roentgenological findings were not considered.

In 60 of 172 cases in which both examinations were negative, no satisfactory clinical diagnosis was made, and in 112 cases the clinical diagnosis included a wide variety of extragastric disorders and diseases.

In 46 of the 355 cases with conflicting gastroscopic and roentgen findings, gastroscopy failed to reveal lesions shown by the x-rays, including 22 cases of benign ulcer, 21 of carcinoma (11 proved at operation or autopsy), 2 of benign polyposis, and 1 case of gastric diverticulum. Conversely, positive gastroscopic and negative roentgen findings were obtained in 309 cases, including 269 cases of chronic gastritis, 26 of benign ulcer, 10 of carcinoma (diagnosis proved at operation or autopsy in 5), 4 of benign polyps (1 with malignant degeneration and 3 with a gastroscopic and roentgenological diagnosis of carcinoma proved to be tumorlike gastritis by histological examination).

In the complete clinical study of gastric disease gastroscopy and roentgen study are invaluable, although not infallible procedures.

JOHN H. MOHARDT, M.D.

Oppenheimer, A.: The Supine Projection in the Diagnosis of Lesions of the Corpus and Posterior Wall of the Stomach. *Am. J. Roentg.*, 1946, 55: 454.

In many patients undergoing roentgenography for lesions of the stomach, a lesion is not suspected or

Fig. 1. Left, the patient is a male, aged 52, with gastric distress. The large ulcer of the posterior gastric wall was not seen in the prone oblique and, right, prone positions, but is well shown in the supine position.

recognized until revealed by supine views. Consequently, spot roentgenograms of an involved area are often omitted and a negative report is made if the supine view is not taken. The long period spent during detailed spot roentgenogram studies of series of patients sometimes causes visual fatigue which is responsible for poor diagnostic results. In more cases than it seems to be realized, accurate roentgenographic technique yields results that are equal in value to those which are obtained with spot roentgenograms.

The author uses the supine and supine oblique projections to demonstrate lesions not ordinarily observed in the upright and prone positions. Although in nearly 80 per cent of the cases the morbid condition can be revealed in the prone, prone oblique, and upright views, in the remaining 20 per cent it cannot be demonstrated unless supine projections are used. This is true especially when the corpus and posterior wall of the stomach are involved.

The author's observations suggest that roentgenography of the stomach in the supine and supine oblique positions is indicated when the clinical manifestations strongly point to a gastric lesion but the usual roentgen methods fail to reveal such a lesion. The technique of the method is outlined in detail.

HAROLD LAUFMAN, M.D.

Dohn, K., and Faber, B.: Invagination of the Stomach. *Acta radiol.*, Stockh., 1945, 26: 56.

The Danish literature had previously reported a case of invagination of the stomach which was diagnosed at post mortem. The present case was diagnosed during life. The case was that of a woman, 71 years of age who was diagnosed on roentgen examination as having an invagination of the stomach. On roentgen examination made 11 days subsequently the invagination had disappeared. About a month later the patient died from other causes, and a post-mortem examination was performed. The fundus of the stomach showed a myoma on a stalk the size

of a green walnut: this was the primary cause of the invagination.

The different types of invagination of the stomach are discussed in this article. Twenty-four cases were investigated in the available literature. The underlying cause of invagination had in all cases been a tumor, which practically always was benign and stalky. Among these cases it was possible to diagnose 6 of 14 by means of roentgen examination. The typical subjective and objective symptoms during life are those of pyloric obstruction.

RICHARD J. BENNETT, JR., M.D.

Tomenius, J.: The Cytological Diagnosis of Gastritis. *Acta. med. scand.*, 1946, 123: 417.

The author presents clinical results of his study of the gastric juices from 15 patients without gastric pathology, and 13 with gastritis. His observations were well controlled. Customary clinical examinations were made: The anamnesis and clinical status were determined, roentgen films of the stomach and duodenal bulb were made, the acidity was determined according to Ibre, and gastroscopy was done. The position of a special tube by which continuous suction was applied separately in the lower esophagus, lower stomach, and duodenum was controlled by fluoroscopy. Fractional samples of the gastric juice, protected by 1.3 per cent solution of bicarbonate dripped continuously into the upper stomach, were obtained. Contamination from saliva could be controlled by the presence of squamous cells in the gastric juice; the quantity of trypsin in the gastric juice was a check on duodenal contamination. The fasting patients were subjected to gastric lavage with from 300 to 400 ml. of tepid water in 30 or 40 ml. portions in the morning. Secretory stimulation was obtained by an injection of 1.0 mgm. per 10 kgm. of body weight. Cellular digestion of the samples obtained was controlled by incubation at 37° C. of neutralized gastric juice.

The conclusion is made that in cases of gastritis an outflow of leucocytes occurs, which has more than 1

to 10 cells per field of vision seen in normal individuals. In 1 case of chronic gastritis no cells were found. In 1 case of pernicious anemia the outflow of cells disappeared after therapy with liver preparations.

JAY P. BARTLETT, M.D.

Moses, W. R.: Diverticula of the Stomach. *Arch. Surg.*, 1946, 52: 59.

Diverticulosis of the stomach is an uncommon condition, as is evidenced by the fact that only about 150 cases have been reported. The most frequent site of occurrence is on the posterior wall near the lesser curvature in the cardiac region. In approximately 30 per cent of the reported cases there have been other associated gastroduodenal conditions, more likely to cause symptoms than the diverticulum itself. About 1 in every 3 diverticula will be the site of adverse symptoms. The condition has no characteristic, or even suggestive, symptoms that would tend to differentiate it from other far more common lesions of the upper gastrointestinal tract. The eventual diagnosis will usually be made only on the observations at autopsy, or at operation; or by the results of several roentgenological studies of the gastrointestinal tract, or by gastroscopic examination. It is easily missed by any of these methods.

A case is presented which illustrates rupture and bleeding into the peritoneal cavity due to a gastric diverticulum. The diagnosis was made clinically by an uncommonly fortunate series of events. This complication of diverticulum of the stomach has not been previously reported in the literature.

JOSEPH GASTER, M.D.

Hartman, F. W.: Curling's Ulcer in Experimental Burns. The Effect of Penicillin Therapy (Correlation of Observations with Other Recent Evidence Regarding the Pathogenesis of Peptic Ulcer). *Gastroenterology*, 1946, 6: 130.

Of 28 control dogs receiving third degree burns over from 50 to 60 per cent of the shaved body surface, all animals examined showed positive blood cultures, and 77.7 per cent developed acute duodenal ulcers. In the case of 10 other dogs with similar burns, penicillin in amounts ranging from 10,000 to 50,000 units daily was given intramuscularly. The penicillin reduced the incidence of duodenal ulceration in these dogs from 77.7 per cent in the untreated control group to 23 per cent in the treated group. This occurred in spite of the fact that (a) penicillin inhibits the growth of only certain types of bacteria, and (b) relatively small and infrequent daily doses of penicillin were given.

The author's experimental data indicate that the local and resulting systemic infection produced in these dogs with burns was of major etiological importance in the total pathogenesis of the acute duodenal ulcers. Congestion and edema of the duodenal and gastric mucosa have been noted in many of the dogs with burns. Evidence has been outlined which strongly suggests that this mucosal congestion constitutes the precursor or background

for subsequent ulceration. It is interesting that these observations harmonize with the recent classical observations of Wolf and Wolf upon their human subject. They too noted mucosal congestion with associated marked increase in the susceptibility of the mucosa to slight trauma as the first stage in the pathogenesis of their experimental ulcers. In their human subject, certain strong emotions were the cause of the mucosal congestion. In the dogs with burns complicated by shock and infection, the shock was presumably the cause of the mucosal congestion. Detailed pathological evidence has demonstrated that the final stage of duodenal and gastric ulceration in these dogs is a corrosive and not a local infectious process.

CHARLES BARON, M.D.

Blader, I., Ruby, V. M., and Shuman, B. J.: Tuberculosis of the Stomach with Special Reference to Its Incidence in Children. *Gastroenterology*, 1945, 5: 474.

Tuberculosis of the stomach is uncommon in all age groups and particularly in children. A review is presented of 61 cases (collected from the literature) of gastric tuberculosis in children 15 years of age and younger. The ratio of incidence of gastric tuberculosis in adults and children is 5 to 1, in contrast to previous reports of lower ratios.

The most common lesion is ulcer, which occurred in 95 per cent of the cases. The pars pylorica and the body of the stomach are more frequently involved than the cardia. Attempts to explain the infrequent occurrence of gastric tuberculosis have been manifold but inconclusive.

Possible routes of infection include hematogenous, lymphogenous, serosal, and mucosal (direct) routes. The authors are in agreement with those who deny the possibility of the mucosal method of infection.

Vomiting, emaciation, and diarrhea are the most frequent symptoms. These, however, are not reliable in making a specific diagnosis, nor are determinations of gastric acidity, gastroscopic examination, and roentgenographic studies of conclusive value.

The diagnosis of gastric tuberculosis in children must be considered in patients with known or suspected tuberculosis who also present symptoms referable to the gastrointestinal tract.

JOSEPH GASTER, M.D.

Riveros, M., and Thompson, Q. C.: Considerations on a Case of Multiple Gastric Polyposis, Hypertrophic Gastritis, and Cancer of the Pyloric Antrum (Consideraciones acerca de un caso de poliposis gástrica múltiple, gastritis hipertrofia y cancer del antro pilórico). *An. Fac. cient. med.*, Asuncion, 1945, 5: 9.

Riveros and Thompson reported the case of a 50 year old single man with vague symptoms of the upper gastrointestinal tract for 10 years, who then developed symptoms of pyloric obstruction with increased gastric motility which could be seen through the abdominal wall.

A subtotal gastric resection was made and he was found to have multiple gastric polyposis, hypertrophic gastritis, and a pyloric cancer producing obstruction.

WILLIAM E. RICKETTS, M.D.

Raimondi, P. J., and Collen, M. F.: Recurrence Rate of Symptoms in Peptic Ulcer Patients on Conservative Medical Treatment. *Gastroenterology*, 1946, 6: 176.

A study was made of the recurrence rate of symptoms in 151 patients with the clinical and roentgenographic diagnosis of peptic ulcer who were treated with a standard conservative medical regimen.

The recurrence rate of symptoms was found to be remarkably constant. During the first year of treatment an average of 5 per cent of the patients each month had a first recurrence of symptoms. At the end of the first year two-thirds of all the patients had suffered a first recurrence. Of those that escaped symptoms the first year, two-thirds had a first recurrence in the second year of treatment.

During the period of observation, from 1 to 2 3/4 years, 39.1 per cent of the patients had but a single recurrence. The majority of the patients treated over 2 years had multiple recurrences.

Only 10.6 per cent of the patients on this therapeutic regimen received no relief of symptoms during a recurrence. Of 106 patients treated over 1 year, 42.5 per cent had symptom free periods lasting from 1 to 2 1/2 years.

Although treatment of the symptoms of active peptic ulcer is very satisfactory (relief was obtained in 90 per cent of patients), the high incidence of recurrences (in 83 per cent of the patients treated for 2 years) indicates that the chief therapeutic problem in the management of peptic ulcer is the prevention of exacerbations.

JOHN J. MALONEY, M.D.

Moore, F.D., Chapman, W.P., Schulz, M.D., and Jones, C. M.: Transdiaphragmatic Resection of the Vagus Nerves for Peptic Ulcer. *N. England J. M.*, 1946, 234: 241.

In 1929 Hartzell, using dogs, demonstrated in a convincing manner three fundamental points relative to the vagus nerves. The first is that section of both nerves decreases the acidity of the gastric contents. The second is that this section cannot be adequately done unless it is made through the chest. The third point is that if the section is technically incomplete, the effect is disappointing and transient. A restudy of the dogs 3 years after the initial operation showed a return of the acidity. This finding prompted the authors to carry out the most complete vagus resection possible in the lower chest and upper abdomen.

Smithwick has shown that a lasting result can best be obtained by radical extirpation of the autonomic system involved. This fact led the authors to perform a vagus resection in which the nerve is resected from just below the lung root to well down on the stomach wall. Smithwick has also shown that the autonomic nervous system regenerates rapidly, particularly through tissue planes and ordinary liga-

tures; therefore, the authors believe that ideally the diaphragm should be cut and interposed between the cut ends of the nerves.

With these considerations in the background, work in this field was begun at the Massachusetts General Hospital, Boston, early in 1944, and to date 15 patients have been operated on. Of the 15 cases, the authors report on 12. These 12 cases represent some of the most difficult therapeutic problems encountered in this field. They were selected because of the long duration and intractability of the symptoms as well as the past and present complications. All of the patients had had one or more rigorous terms of hospital medical treatment in an attempt at relief. They were chosen in the hope that good or bad results would soon become apparent, and with the idea that a maintained good result was significant and not due to chance factors.

The authors have routinely novocalinized both vagus nerves above the point of manipulation and have given rather large doses of atropine either before or during the operation.

The report of the clinical results in these 12 cases must be regarded as an interim one, because it will be many years before this operation can in any way reach final evaluation.

Following operation, as a general rule, the patients were allowed to eat and drink anything they wished, including alcohol and coffee, since it was believed that the operation would not be put to an adequate test if a patient was carried along on conscientious medical therapy.

The place that this operation will ultimately occupy in the surgical armamentarium is at present not clear. In view of the present limited knowledge and experience with the operation, little can be said concerning its limitations. It is clearly not indicated in acute perforations, acute massive hemorrhage, or advanced cicatricial obstruction, and these situations should be dealt with by appropriate surgical maneuvers other than vagus resection. Beyond these obvious contraindications, the authors have not yet found criteria by which patients can be excluded from the possibility of benefit from this procedure.

The occurrence of bleeding in the past is no contraindication to the operation.

Gastric ulceration proximal to the pylorus should be approached with the greatest caution, so far as this operation is concerned. The reason for this is that although the diaphragm is open, the region of the ulcer cannot be adequately visualized and palpated, and even if it could be, it is often impossible to differentiate ulcer from cancer. Resection should therefore usually be employed in such cases.

Patients who have had other surgery, such as pyloroplasty, posterior gastrojejunostomy, or gastric resection, and who present themselves with renewed ulceration are ideal subjects for this procedure. The previous surgery does not in any way complicate the operation, and it may be carried out with excellent relief of symptoms in cases in which renewed attack on local structures through the ab-

domen would be technically complicated, with the end result open to question.

The largest group of cases in which this procedure seems to be of value is that of young or middle aged men with a long history of peptic ulceration, possibly with previous perforations or hemorrhages, unobstructed and not acutely bleeding, who have been refractory to careful medical therapy and who have severe ulcer pain in times of stress, which can be relieved transiently by the usual antacid, milk, or food. This type of patient obtains a uniformly good result from the procedure, but the duration of the relief is at present unknown.

JOSEPH GASTER, M.D.

Bonorino, C., D'Alotto, V., and Ramos, M. M.: Retrobulbar Ulcers of the Duodenum (*Las úlceras postbulbares del duodeno*). *Arch. argent. enferm. ap. digest.* 1945, 20: 340.

The authors found 6 cases of ulcer beyond the duodenal bulb in a series of 2,135 duodenal ulcers studied at the Dispensary of Gastrointestinal Diseases in Buenos Aires. These ulcers were located above the ampulla of Vater.

The somatic as well as the clinical symptoms were not different from those of ulcers located at the duodenal bulb. Two of such cases has massive bleeding.

The authors stressed the fact that frequently these ulcerations have been confused with diverticula of the duodenum. WILLIAM E. RICKETTS, M.D.

Brunschwig, A., and Tlnholz, J. C.: Surgical Treatment of Malignant Tumors of the Duodenum Exclusive of Those Arising from the Papilla of Vater. *Surg. Clin. N. America*, 1946, 26: 163.

The authors review the literature on resections of the malignant tumors in the duodenum, exclusive of those arising from the papilla of Vater, and report their personal experience with 5 cases attacked surgically.

The surgical attacks consisted of:

1. Resection of the tumor and portions of the duodenal wall involved
2. Resection of a segment of duodenum and adjacent segment of the head of the pancreas
3. Pancreatoduodenectomy to resect the entire duodenum and head of the pancreas.

In the first case roentgenograms revealed a polypoid tumor mass in the lower portion of the second segment of the duodenum. Operation consisted of exposure of the carcinoma in the second portion of the duodenum by a longitudinal incision through the anterior wall of the first and second portions of the third segment of the duodenum. Repair of the resected portion of the posteroserial wall with the tumor was then made by interrupted sutures. The transected common bile and main pancreatic ducts, respectively, were transplanted into the upper angle of the wound in the duodenum. The resected tumor arose in the lower portion of the second segment of duodenum and involved the papilla of Vater secondarily, compressing it upward but not infiltrating it.

Histopathological study revealed this to be a medullary carcinoma of the duodenum. The patient is well and normally active 7 years and 10 months after operation.

In the second case roentgenograms revealed a stenosing lesion that was thought to be in the terminal pylorus. At laparotomy a scirrhous carcinoma was found which involved the first segment of the duodenum and infiltrated downward into the head of the pancreas. There were no apparent metastases. The growth was removed by a segmental resection through the lower one-third of the stomach and by transection of the duodenum at the junction of the lower two-thirds of the second segment with its upper third. The common bile duct and portal vein were not injured. For restoration of gastrointestinal continuity, a posterior poly gastroenterostomy was performed.

Histopathological study revealed an adenocarcinoma arising in the first segment of the duodenum and infiltrating the subjacent pancreas. The patient was well for one year, then presented a palpable epigastric mass that was moderately tender. Laparotomy was again performed, at which time a dense fist sized mass of recurrent carcinoma was present over the head of the pancreas. In the attempt to resect this the portal vein was opened and its ligation was necessary. The patient succumbed in shock 3 hours later.

In the third case roentgenograms revealed a large ulceration of the wall of the third portion of the duodenum. At operation a large spindle celled sarcoma arising from the third portion of the duodenum with ulceration at one point was found. The neoplasm partially surrounded the superior mesenteric vessels and also extended posteriorly and superiorly behind the head and body of the pancreas. Metastatic lymph nodes were present along the greater curvature of the duodenum. A segmental resection was performed by transecting the jejunum about 3 c.c. beyond the ligament of Treitz and invaginating the distal end. The duodenum and the head of the pancreas were transected about 2 cm. below the papilla of Vater. Gastrointestinal continuity was re-established by duodenoduodenostomy. The pancreatic and common bile ducts were not injured.

Histological study revealed a spindle celled sarcoma. Sections of several lymph nodes revealed metastatic sarcoma. The patient is alive and well 3 years after operation.

In the fourth case the patient had a round celled sarcoma, or lymphosarcoma, involving the duodenum from the upper curvature almost to its termination. The patient in the fifth case had a carcinoma of the third segment of the duodenum invading the adjacent lower portion of the head of the pancreas and its uncinate process. The former patient, who was in a poor nutritional state, died on the seventh postoperative day; the latter lived 3 months after operation, but died from a deep abdominal abscess that developed after he returned home.

Extensive malignant neoplasms of the duodenum require complete excision of the duodenum. This can be accomplished only by concomitant resections of the head of the pancreas.

Pancreatoduodenectomy was originally devised for resection of carcinomas of the head of the pancreas. However, large duodenal neoplasms will usually involve the head of the pancreas and therefore this method of operation is also indicated for such growths.

Reconstruction of the upper alimentary tract after one-stage pancreatoduodenectomy consists of: choledochojejunostomy, cholecystojejunostomy, gastrotrojunosomy (Billroth II), implantation of the transected neck of the pancreas into the jejunum, and enterointerostomy between the jejunal loops going to the biliary tract.

Operations as described should be carried out under continuous spinal anesthesia, and the systolic blood pressure should be maintained at at least a pressure of 100 mm. of mercury.

General conclusions are not yet possible in regard to the surgery of primary malignant neoplasms of the duodenum. Pancreatoduodenectomy is the most radical procedure, but good results have been achieved with more conservative measures. Each patient presents individual problems which must be evaluated if the surgeon is to carry out the best operation for that patient.

JOHN H. MOHARDT, M.D.

Etchepareborda, J. A., and Stapler, N. M.: The Value of Roentgenology in the Diagnosis of Tuberculosis of Bauhin's Valve (El valor de la radiología en el diagnóstico de la tuberculosis de la válvula de Bauhin). *Arch. argent. enferm. op. digest.*, 1945, 20: 291.

The authors discussed the roentgenological aspects of tuberculosis of Bauhin's valve of the cecum, illustrating the different types of lesions and describing 5 varieties.

In the first type there was a stenosis of the valve which produced dilatation of the ileum.

In the second the incontinence of the valve allowed the passage of gases to the small bowel; this could be visualized with x-rays.

In the third there was the Bonnamour-Bernay-Badolle sign which consists in the deformation of the cecum and is produced by the intussusception of the ileum.

In the fourth was found the Fleischner sign, a thick diffuse infiltration of the valve with retraction of the cecum, simulating an opened umbrella of which the handle is the ileum.

In the fifth was found the "crown sign," produced by the infiltrated borders of the cecal valve. An oval or circular lesion is found where the ileum opens into the cecum.

One case of tuberculosis of the cecal valve was reported, and a case in which such a lesion was suspected was found to be normal at operation.

WILLIAM E. RICKETTS, M.D.

Glenn, P. M., and Read, H. S.: Tuberculous Ulcerative Colitis or Ulcerative Colitis with Superimposed Tuberculous Infection. *Gastroenterology*, 1946, 6: 9.

A case of ulcerative colitis with ischio-rectal abscess, from which tubercle bacilli were isolated, is reported. The role of the tubercle bacillus in this patient is a perplexing problem. The ulcerative tuberculous type of intestinal lesion is almost invariably secondary to a tuberculous focus elsewhere in the body. The respiratory tract is most often involved and the bowel lesions are usually manifestations of an overwhelming infection. McGlannon and others have expressed the belief that tuberculous lymphadenitis and tuberculosis of the genito-urinary tract may be primary foci for intestinal tuberculosis. Tuberculosis in other organs is present in from 95 to 97 per cent of the cases. Babinski was unable to find pulmonary lesions in only 5 of 285 subjects with intestinal tuberculosis who came to autopsy. Primary intestinal tuberculosis is a rare disease in the United States.

Clinically, the patient had no pulmonary symptoms, and produced no sputum, and repeated gastric washings revealed no acid fast organisms. However, his mother died at the age of 47 in a tuberculosis sanitarium and 1 brother had tuberculosis.

Although a calcified Ghon complex was present in the lungs, no active pulmonary tuberculosis was demonstrable at autopsy.

The girdlelike ulcerations of the colon were suggestive of tuberculosis, but the histological evidence was not conclusive. In the rectum and the ischio-rectal abscess, the histological picture was indicative of tuberculosis.

The findings indicate that tuberculous infection played a definite role in this disease. The temporary improvement in association with sulfa and penicillin therapy may have been due to the effect of these agents on the pyogenic organisms. The possibility that the tuberculous infection was a superimposed infection is purely speculative. The superimposition of tuberculous infection upon a previous idiopathic colitis must be considered a possibility.

JOHN H. MOHARDT, M.D.

Vernengo, M. J., and Villafañe, E. P.: Solitary Diverticulitis of the Cecum (Diverticulitis solitaria del ciego). *Prensa med. argent.*, 1946, 33: 506.

The authors' patient, a male 47 years of age, had been troubled for a long time by gastric disturbances with the sensation of heaviness in the abdomen following meals. Twenty-four hours before admission to the hospital there had been an onset of diffuse abdominal pain, which later localized in the right iliac fossa. Inspection disclosed some elevation of the abdominal wall in the right lower part of the abdomen, the underlying mass apparently moving with respiration. The mass was about 5 cm. long and 3 cm. wide, extremely painful on manipulation, and slightly mobile both vertically and horizontally. A certain amount of tympany and a few borborigmi could

Fig. 1. Roentgenogram made with an opaque enema

be elicited. Contrast roentgenography brought out the condition shown in Figure 1, which is not discussed and which evidently did not lead to clarification of the condition, since the operation was undertaken for a possible typhlitis of undetermined etiology or on a diverticular basis.

At operation under spinal anesthesia, the incision was made between the second and third lumbar spines and carried through the rectus abdominus muscle. Raquiperchain, 7.5 mgm. with 8 cm. of spinal fluid, was used. A small amount of serous fluid in the peritoneal cavity and an inflammatory mass on the outer side of the cecum were found. The mass was firmly adherent to the parietal peritoneum and measured about 4 by 3 cm. in size. It was freed by resection of the parietal peritoneum. The inflammatory condition had extended over on to the cecum for an area of about 5 by 3 cm. The ileocecum was resected, the ileum to about 10 cm. from the ileocecal valve and the cecum to about 3 cm. above the valve. An ileocolonic laterolateral isoperistaltic anastomosis was effected with catgut and linen sutures. Careful peritonization of all the raw surfaces and closure, layer by layer, of the abdominal wall were done without drainage.

The postoperative course was normal, and the patient was up and about on the twelfth day.

JOHN W. BRENNAN, M.D.

Vignard, P.: Reflections on the Retrocecal Appendix with Regard to an Unusual Complication (Réflexions sur l'appendicite sous-coecale à propos d'une complication rare). *Lyon chir.*, 1945, 40: 602.

In 2 instances, rather atypical symptoms of appendicitis led to laparotomy and the finding of a

chronically inflamed cecum and retrocecal appendix. A difficult appendectomy was carried out, including ligation at the base and inversion of the stump into the cecum in the usual manner, with a gauze drain to the surface for 2 or 3 days following operation. In the 1 case, after 2 days, and in the other, after 14 days, copious bleeding appeared in the form of blood in the stool, which persisted until the patients were rendered dangerously anemic. In 1 case repeated blood transfusions were required before the condition could gradually be induced to disappear.

These 2 experiences raise a question in the author's mind as to the advisability of burying the ligated stump of the appendix in the cecum when both the appendical walls and those of the neighboring cecum are apt to be friable and congested. There is also the question as to the need, on occasion, of reopening the laparotomy wound and opening the cecum itself in order to get at the bleeding point. In neither of the author's 2 patients did he do this, but he does not pretend that he acted in the most logical manner, and he entreats others who may have found themselves in analogous situations to relate to him their experiences and their opinions concerning this matter.

JOHN W. BRENNAN, M.D.

Manzella, M.: Acute Volvulus of the Appendix (Volvulus agudo del apéndice). *Rev. As. med. argent.*, 1945, 60: 1362.

Manzella reports a case of acute volvulus of the appendix vermiformis, which was preoperatively diagnosed as acute phlegmonous appendicitis. At operation, the appendix was found to be covered by an apparent phlegmonous finger of omentum; on removal of the omentum, an anemic knottlike twist of the appendix was revealed at its proximal third level. Above the knot and up to the cecum, the appendix was congested. Below the knot the appendix graduated into a gourd shaped necrotic tip. The mesoappendix appeared normal. The rotation was in the longitudinal axis from left to right.

A considerable discussion concerning the hypothesis of torsion of the appendix was given.

STEPHEN A. ZIEMAN, M.D.

Vallazza, E.: Carcinoid of the Ileocecal Appendix (Carcinoid del apéndice ileocecal). *As. Ital. maternidad*, B. *Air.*, 1944, 6: 111.

This affection has many synonyms. It has been called pseudocarcinoma, lipid cancer, argentaffine tumor, cancer of the basal cells of the intestines, and neoplasm of the mucosa.

Carcinoid is a rare entity, and one that is most difficult to diagnose. It occurs between the ages of 20 and 30 years, and most frequently in women. The origin of the tumor is in dispute—some consider it as arising from the cellular structure of the glands of Lieberkuhn, others associate it with certain eosin cells, and still others think it arises from lymph follicles.

termining the degree of mechanical obstruction by use of duodenal intubation in discovering whether bile is flowing into the duodenum in satisfactory amounts. If it becomes evident that one is dealing with a mechanically malfunctioning anastomosis, then re-exploration is indicated if the condition of the patient warrants further surgical treatment.

One probably obtains the poorest results in all surgery from attempts at reconstruction of the biliary duct system. However, when one considers the hopelessness of the situation without surgical intervention, the results can be viewed much more optimistically. Thirty-six per cent of all the patients were well 2 years or more after the reconstructive operation and a total of 67 per cent were alive. Of the 31 per cent who had symptoms of cholangitis and obstruction that persisted, a half required further attempts at reconstruction.

Actually in certain selected cases, reconstruction operations can be very satisfactory. If injury or severance of a common duct is recognized immediately and repaired, the ultimate result is quite satisfactory. Too, when there remains a long segment of common duct and the diameter is sufficient to enable the surgeon to do choledochoduodenostomy without the use of a Mayo-Sullivan tube or catheter, the results are gratifying. Sixty-two per cent of these patients were well 2 to 12 years after operation and less than a third of the 62 per cent had had temporary symptoms of cholangitis. If one elects to use a catheter or tube in performing choledochoduodenostomy, the results may be only slightly less gratifying according to our study, in which 55 per cent were living and well 2 to 12 years after the operation. When a T tube reconstruction was used the results proved only two-thirds as good as when choledochoduodenostomy was performed without a tube. Why this is true is not entirely apparent; it may be that removal of the T tube causes injury to the anastomoses and allows subsequent stricture.

When the common duct is destroyed and one is compelled to use the hepatic duct in performing hepaticoduodenostomy, the results are the least favorable of all the recon-

structions. Only 28 per cent of the patients were alive and well 2 to 12 years later.

It is surprising to discover that 4 (21 per cent) of the patients who underwent hepaticostomy in which an external biliary fistula was established were entirely well and without biliary drainage. A spontaneous internal fistula developed, and the patients gave a history of discharge of food particles for a time prior to closure of the external fistula. Therefore, if one is compelled by necessity to resort to hepaticostomy when an external biliary duct is not identified, all hope should not be abandoned. In one case in which there was a permanent external biliary fistula, a visit at the clinic 4 years later revealed the patient to be in relatively good health and able to perform her duties. She takes her own bile by mouth and her intake of calcium is high. A high intake of calcium must be maintained to prevent osteoporosis, which develops in patients who lose the biliary excretion.

Progress has been made in the management of a complication that has arisen in the evolution of biliary surgery. The place that the vitallium prosthesis will come to occupy remains to be ascertained. However, we wish to reiterate that the best treatment for benign stricture of the bile ducts is prevention, which can result only by impressing the seriousness of the problem on surgeons and by their adherence to rigid care in actual identification of the structures that they are handling when performing biliary operations.

SUMMARY

Benign stricture of the bile ducts is a tragedy for the patient and for the surgeon. In nearly three-fourths of the cases such a tragedy might well have been averted. However, there are certain strictures, at least 12 per cent in this study, which can best be explained on the basis of low-grade chronic inflammation, so called chronic obliterative cholangitis.

Although surgical results are far from being all that can be hoped for, nevertheless, surgical treatment does offer a real hope in certain types of stricture, for after choledochoduodenostomy 55 to 62 per cent of the patients

Of the 84 cases reported by the author, only 3 showed evidence of metastasis. With complete surgical excision the prognosis is good; however, if extension to the glands has occurred, the prognosis is bad.

It is nearly impossible to make a clinical diagnosis because the symptomatology is indicative of the organ affected. Vallazza's patient was diagnosed as having chronic appendicitis. At operation a tiny tumor was found on the top of the appendix. The pathological report was returned as carcinoid of the ileocecal appendix. The patient has been examined periodically for 1½ years, and there has never been any evidence of recurrence. STEPHEN A. ZIEMAN, M.D.

Castro, J.: Cancer of the Rectosigmoid and of the Sigmoid (Cancer recto sigmoideo y sigmoideo).
Bol. Soc. cir. Chile, 1945, 23: 121.

The material here reported consists of 27 patients with rectal and anorectal cancer, and 10 with sigmoidal cancer. With the exception of 7 cases (seen in private practice, but with the same criteria of treatment), they were observed on the surgical service of F. de Amesti at the hospital of San Salvador, Santiago, between the period from June, 1938 to July, 1945. All of the cases were instances of the relatively radioresistant adenocarcinoma, with the exception of 1 case of solid papillary cancer of the intermediate type of anorectal origin which had invaded the rectum secondarily; however, this case was given the same treatment as the others. The majority of the patients were of middle age, from 40 to 60 years old, and there was a slight predominance of the male sex. It took the usual extended length of time before the condition was properly recognized. There were 12 rectal and rectosigmoidal cancers and 2 carcinomas of the iliac sigmoid in which the condition was not recognized until more than a year after the initiation of symptoms, and in 1 instance 2½ years had elapsed before the patient entered the hospital. The usual symptom leading to diagnosis was constipation, but intervention for acute obstructive symptoms—diarrhea, hemorrhage, pain, tenesmus, and colicky attacks—was necessary in only 3.7 per cent of the cases. Secondary anemia was present in 10 instances, but was due to small continuous blood losses rather than to massive hemorrhage.

These conditions had to be taken into consideration in preparing the patients for operation. It was necessary to do a decompressive operation as an emergency measure only once; however, a considerable number of the patients gave a history of acute or subacute obstructive conditions which had been relieved by medical measures. The poor quality of the material required long, careful preoperative preparation of the patient in order to combat the dehydration, anemia, avitaminosis, and vascular disturbances. During a preparative period of some 2 weeks or more, an albumin-rich, high-calorie diet (poor in residue), blood transfusions in cases of anemia, plasma transfusions in shock and hypoproteinemias, and copious quantities of fluid (given orally or

intravenously) were administered; this permitted types of operations that were highly radical in character. The bowel was kept relatively empty with laxatives and enemas, but when the obstructive manifestations were more severe, a cecostomy, colostomy, or enterostomy was done to decompress the bowel and improve the general condition of the patient. After operation the use of an indwelling Miller-Abbot tube for 4 or 5 days proved invaluable. The sulfa drugs, preferably given orally before and after operation, gave the impression of suppressing pulmonary complications. Sulfaguanidine, associated with sulfathiazole, was given from 4 to 6 days preoperatively and injections were continued for 4 or 5 days postoperatively. The author believes that a medical internist and a urologist should always be brought into consultation in the preoperative period, and cites a case history in which the urologist stated that the recurrence in the bladder was undoubtedly the result of an extension of the tumor to the bladder which should have been detectable preoperatively.

During the operation, blood or plasma in amounts up to 500 or 1,000 c.c. were administered and the procedure was repeated that same evening or the next day. No particular method of anesthesia was employed exclusively, the choice of modality being left largely to the judgment of the anesthetist.

Twenty-one rectal and rectosigmoidal, and 10 iliac-sigmoidal carcinomas were brought to operation; of the former, 10 underwent a purely palliative procedure (colostomy) and 10 were operated upon radically, 9 by the one-stage, abdominoperineal, somewhat modified technique of Miles, and 1 by two-stage abdominoperineal resection. One additional case was subjected to colostomy, but the patient refused resection. There were 2 deaths in the hospital (1 from peritonitis and 1 from operative shock); 2 patients died somewhat later of metastasis; 1 patient survived for 3 years and then died of pulmonary metastases; 1 patient operated on in 1941 has not been heard from; and 1 with the bladder condition cited earlier died of local recurrence. Therefore, 4 patients are still alive; they are well after the following periods: 6 years and 2 months (1), 2 years (2), and 3 years (1). Of the 10 cancers of the ileum and sigmoid, 2 were resected by Rankin's method for tumors of this region; 3 patients underwent the Mikulicz operation, 2 were subjected to resection with end-to-end anastomosis, 2 underwent the palliative operation of Hartmann, and 1 was subjected to a cecostomy. There were no operative deaths; 1 patient is perfectly well after 2 years and 10 months; 1 was reoperated upon 5 years later for another cancer of the ascending colon and now, 2 months later, is entirely well; 1 died after 2 years and 6 months of hepatic metastases; 1 was re-examined 2 years and 9 months after operation and was found to be perfectly well; 1 died 2 years and 2 months after operation because of recurrence at the point of the enteroanastomosis; 1 who had undergone the Hartmann operation died 4 months later of abdominal carcinosis; the other patient undergoing the Hart-

mann operation was still well 5 months after the operation, and the last patient (Mikulicz operation) has not been heard from since operation.

The most troublesome and persistent postoperative complication cited by the author was that of male impotence, which developed in 4 of his patients and seemed to be irreparable.

In the discussion period, RAHUSEN cites the diagnostic value of the passage of mucus independently of defecation and the purely palliative value of radiotherapy in the adenomas, with preliminary derivative operative measures to reduce the inflammatory factor which, according to this author, appreciably inhibits radiosensitivity. LABACA notes that tumors of the right colon exhibit periods of diarrhea, while those of the colon descendens are characterized by obstinate constipation. He has observed that propagation of the neoplasm takes place much more often by contiguity than by lymphatic dissemination.

JOHN W. BRENNAN, M.D.

Duckerts, J.: A Contribution to the Study of Anorectal Cancer (Contribution à l'étude des cancers anorectaux). *Rev. belge. sc. med.*, 1944, 16: 125.

This careful and somewhat laborious study of anorectal cancer is based on 26 cases seen between 1927 and 1942 at the Anticancer Center at the University of Liege. The article is written in the French style of thesis, taking up methodically every aspect of the subject. There is, for instance, a discussion of the anatomy, frequency, etiology, pathological anatomy, microscopic and macroscopic extension (local and distant), diagnosis, treatment, and results. In each of these sections the views of other authorities are taken up and discussed, and then these views and statistics are compared with the cases in this study. The work has been carefully done and is well documented and may be well worth consulting by anyone especially interested in this type of work.

Anorectal cancer is rare at this clinic representing 1 per cent of all malignant lesions; however, it is a serious disease as only 1 case of the 26 was cured, 3.8 per cent. The poor results are attributed to delay in the diagnosis, almost half of the patients being inoperable when first seen. Both the patient and the physician were deemed blameworthy in not resorting earlier to biopsy. There was a tendency on all sides to regard the disease as of a chronic inflammatory nature. Furthermore, favorable response to x-ray and radium therapy delay the use of more radical measures until they in turn are unsuccessful. The average patient presenting himself with what he considers a relatively minor lesion is astounded when it is proposed that he have a temporary colostomy, a wide surgical excision of the lesion, and a course of radium or x-ray therapy. This form of treatment instituted at an early date is, nevertheless, the only way of obtaining a good result.

A biopsy was obtained in 22 of the 26 cases, and it was found that there were 11 epitheliomas and 11

adenocarcinomas. It is stated that not all the lymphatics of the cutaneous region of the anus go to the inguinal lymph nodes, but that some follow the superior hemorrhoidal artery to the inferior mesenteric nodes. The earliest symptoms are pruritus, bleeding, and pain; later there may be hemorrhage, difficulty in defecation, tenesmus and distortion in the size and shape of the stools. The differential diagnosis is from tuberculosis, actinomycosis, chancres, fissures, fistulas, thrombosed or ulcerated hemorrhoids, condyloma, and fibrous stricture of the rectum. Actually, the diagnosis depends on biopsy. The treatment of choice is a colostomy followed by wide surgical excision of the lesion and either x-ray or radium therapy. ADRIEN VER BRUGGEN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Flynn, J. E.: Pyogenic Liver Abscess. *N. Engl. J. M.*, 1946, 234: 403.

Pyogenic organisms may enter the liver by one of the following ways: through the portal vein from organs drained by it, from blood-borne infections through the hepatic artery, by direct extension from a contiguous infection, and from trauma. The organisms that cause pyogenic abscesses are generally sensitive to the sulfonamides or penicillin. These organisms usually are the colon bacilli, streptococci, and staphylococci. The pus is frequently sterile in liver abscesses.

Two currents of blood in the portal vein have been demonstrated, the one from the superior mesenteric vein which leads to the right lobe of the liver, and that from the inferior mesenteric and splenic vein which leads to the left lobe.

Grossly, the liver is enlarged and the abscesses are usually multiple. Multiple abscesses give the liver a mottled appearance. The usual symptoms are chills, fever, pain, and profuse sweating. With acute suppurative appendicitis complicated by pyelophlebitis and multiple abscesses of the liver, fever is of the "picket-fence" type and is usually accompanied by daily chills. Pain is felt in the right upper abdominal quadrant and is usually constant. Jaundice occurs infrequently and is usually a late serious sign. The elevation and immobility of the diaphragm, usually on the right side, as seen by means of x-rays are of great diagnostic value. Exploratory aspiration of the liver for the detection of pus is dangerous and should not be done.

Death occurs in from 50 to 95 per cent of the cases. Incision and drainage is the proper treatment. An extraperitoneal anterior or posterior approach is made, according to the location of the abscess. Chemo-therapy should play a significant role in the treatment. If an operation is performed, a culture is important to determine what therapeutic agent is to be used.

The author reports a case of multiple pyogenic abscess of the liver due to nonhemolytic streptococci with no demonstrable focus. The organism was sen-

GYNECOLOGY

ADNEXAL AND PERIUTERINE CONDITIONS

Blackwell, W. J., Dockerty, M. B., Masson, J. C., and Mussey, R. D.: Dermoid Cysts of the Ovary; Their Clinical and Pathological Significance. *Am. J. Obst. Gyn.*, 1946, 51: 151.

For the purpose of this study, the records in 225 consecutive cases of dermoid cysts of the ovary removed at operation in the Mayo Clinic were reviewed. One hundred consecutive tumors of this group were examined macroscopically, and from 10 to 15 sections were removed from the cyst wall for microscopic study. In a few instances, the size of the tumor permitted the selection only of from 2 to 5 sections; but in every cyst, these sections were taken at scattered areas in order that the structures of the cyst wall should be well represented.

These data permit the following conclusions:

Ectodermal derivatives were present in 100 per cent of the tumors, mesodermal structures in 93 per cent, and endodermal derivatives in 71 per cent.

The high percentage of mesodermal and endodermal elements was due to the fact that multiple sections were examined microscopically. Serial sections would probably have revealed more.

The term "dermoid" is inaccurate and should be replaced by the term "cystic teratoma."

The hypotheses that have been advanced to explain the histogenesis of these neoplasms do not explain their origin adequately.

These tumors occurred with equal frequency in each ovary. Twelve and four-tenths per cent were bilateral. The average diameter was 8.2 cm. The incidence of cystic teratomas was 5 per cent of all ovarian neoplasms. Malignant lesions occurred in 3 per cent of the cystic teratomas. Symptoms associated with these cysts had no differential diagnostic value.

Surgical removal was the treatment of choice, but, when possible, resection of the tumor was done to conserve ovarian function.

Numers, C. von: A Contribution to the Case Knowledge and Histology of the Brenner Tumor. *Acta obst. gyn. scand.*, 1945, 25: 114.

The author describes 2 cases of Brenner tumors from the Helsingfors University Gynecological Clinic. One of these was a typical case of solid Brenner tumor, while the other was a Brenner tumor combined with a pseudomucinous cystadenoma. In addition, he describes 2 cases in which ovarian tumors containing Brenner epithelium and pseudomucinous epithelium were definitely malignant, both histologically and clinically.

The author suggests that while none have yet been described, there may well be malignant forms of the Brenner tumor. The last 2 cases described may represent examples. DANIEL G. MORTON, M.D.

EXTERNAL GENITALIA

Papanicolaou, G. N.: A General Survey of the Vaginal Smear and Its Use in Research and Diagnosis. *Am. J. Obst.*, 1946, 51: 316.

The use of the vaginal smear for determining the time of ovulation requires considerable training and experience. The interpretation of findings is often difficult. Local infections (bacterial or parasitic) causing leucorrhea tend to modify and obscure the normal picture.

A complete evaluation of the normal sex cycle in women requires an examination of vaginal smears not only during the follicular and postovulatory stages but during all phases of the cycle.

One field in which the progress has been rather slow is that of the diagnosis of pregnancy. Changes typical of gestation appear in the vaginal smear as early as the thirty-eighth or fortieth day and become more accentuated in advanced stages.

In normal gestation one can recognize some abnormal features suggestive of threatened abortion, such as blood, excessive mucus, pronounced acidophilia, or intracellular blood pigmentation. In abortions and ectopic pregnancies, one usually finds moderate bleeding with high fibrination, marked acidophilia, and modified pregnancy or postpartum cells. A point of interest and of some diagnostic value in abortions is the increase in number and the phagocytic action of the histiocytes and the polymorphonuclears. They engulf and destroy not only bacteria and detritus, but also erythrocytes.

The application of the smear test as a method of evaluating ovarian insufficiency and as a guide in hormonal therapy has since been greatly extended, and its value is now being generally recognized.

Smear reports for cancer should be conservatively worded and the findings corroborated as often as possible by curettage or biopsy before any major operation is decided upon. No case should be reported as definitely positive unless the evidence is overwhelming.

Although the preparation and staining of smears is relatively easy, their interpretation is rather difficult. It is based on cytological criteria and requires special study and training.

The nuclear changes of cancer cells seem to offer the most reliable diagnostic criteria. One should refrain from basing a positive diagnosis exclusively on the presence of modified superficial cells. It is also unsafe to consider as absolutely conclusive the vacuolization of cells or their infiltration by leucocytes, as these changes may occasionally be found in other conditions, such as hyperplasia, metaplasia, or endometritis.

Evidence is presented that neoplasms of the urinary organs, including the bladder, prostate, and kidneys, can be detected by the smear method,

patient at the time of injury, and the presence or absence of associated injuries are definite factors affecting the mortality. There is no group of wounds which requires more early, energetic teamwork and co-operation on the part of the entire hospital staff and nursing service than gunshot wounds of the abdomen, and a recognition of this fact will be an appreciable factor in the reduction of mortality from such injuries.

CHARLES BARON, M.D.

Wagner, A.: Four Cases of Diaphragmatic Intumescence. *Acta radiol.*, Stockholm, 1945, 26: 239.

The author has recently seen 4 patients of whom chest films showed a rather large rounded shadow occupying the angle between the right cardiac border and the dome of the diaphragm, each of the shadows being of a different etiology although all were similar in appearance. Barium by mouth showed one of these shadows to be that of an eccentric hernia of the cardioesophageal opening, which was believed to be associated with a congenitally shortened esophagus, in a boy 6 years old with no complaints referable to the anomaly.

The second case was that of a woman 63 years old with hypertension, dyspnea, ascites, ankle edema, and jaundice. Chest films showed a normal appearing heart, but revealed a rounded shadow occupying the right pericardiophrenic angle. Barium given by mouth revealed no relationship of this mass to the gastrointestinal tract and kymography showed that the tumor did not move when the patient held her breath; however, it did move during respiration and was more pronounced during inspiration. A definite diagnosis could not be arrived at roentgenologically. Autopsy confirmed the clinical impression of cirrhosis of the liver with ascites and chronic perihepatitis, and showed that the bulge in the diaphragm was due to the formation of an encapsulated serous cavity between the liver and the diaphragm.

The third instance occurred in a man of 74 years who complained of a sensation of slight pressure in the chest and palpitation. His blood pressure was 160/90. The electrocardiogram and roentgen examination of the biliary and gastrointestinal tracts revealed nothing abnormal. The chest films, however, showed two rounded shadows bulging into the pericardiophrenic angle, and medially, a suggestion of arched extension of the pericardium across the intumescence. The large tumor mass did not pulsate. No certain diagnosis was established, but the author believed this mass was probably a lipoma arising from subpericardial adipose tissue. The author makes reference to a similar case published by Sauerbruch in which operative proof was obtained.

The fourth case was that of a man 24 years old, a farmer and football player, who had been well until the age of 18 when he developed palpitation for 6 months. At that time his heart was found so far to the right that his physician diagnosed situs inversus. Two years later the symptoms recurred and were accompanied by severe pain. The electrocardiogram was normal. Chest films showed the heart to be displaced to the right but of normal size and shape, and in the right pericardiophrenic angle, independent of the heart and somewhat posterior to it, but closely related to the diaphragm, was a rounded mass the size of a hen's egg. There was no evidence of associated pulmonary inflammation or atelectasis although the adjacent pulmonary vessels were somewhat distorted. Kymography revealed no significant pulsation, and when barium was given orally no relationship was found to the esophagus or gastrointestinal tract. At operation a portion of normal liver was found to have herniated through the diaphragm. A constricting groove was split, the hernia reduced, and phrenicotomy done.

LILLIAN DONALDSON, M.D.

small, and (2) the bleeding may have been the result of hyperemia due to pelvic inflammation which should have been cleared up before treatment was started by means of short waves, sulfonamides, or protein therapy.

The 16 successful cases are divided into three groups, a typical case history is given in each group. The first group consists of 10 cases in which

The 16 successful cases are divided into four groups, a typical case history being given briefly for each. The first group comprised those patients in whom the bleeding ceased with the first treatment and the subsequent menstrual cycle was normal—in some instances menopause. The case cited in exemplification of this group was that of a woman of 46 years, who had closed an intense proliferative phase of the endometrium (anovular cycle). Microcurette gave testosterone propionate the use of 250 mgm. of abnormal bleeding and 3 months later a microcurette of the mucosa showed it to be in repose with a tendency toward atrophic changes (menopause). In the second group were the women in whom the bleeding was reduced but not completely stopped. In the third group were the women in whom the bleeding was reduced but not completely stopped. In the fourth group were the women in whom the bleeding was reduced but not completely stopped.

In the second group were the women in whom the reduction of the bleeding occurred abruptly following several monthly treatments and the cycles became regular thereafter. The illustrative case was that of a woman of 42 years, who suffered with metrorrhagia every 15 days. The first dose of testosterone consisted of 125 mgm. The first dose of 75 mgm. each were given at two month intervals, which resulted in a tapering off of the bleeding with ultimate normalcy of the cycle.

The third group included 4 cases of the treatment produced a complete cure of the hemorrhage.

The third group included the patients in whom the treatment produced an actual cessation of hemorrhage, followed by a period of amenorrhea of variable duration and then by subsequent normal periods. The case history reported was that of a 31 year old female with biopsy findings of typical glandular hyperplasia of the endometrium, in whom injections of 50 mgm., 25 mgm., and 25 mgm. 21 daily intervals resulted in the cessation of abnormal bleeding. This condition then persisted for 2 months, but after this time no further abnormal bleeding appeared.

The fourth group included the cases in which the periods were regular for some time after treatment, but the hemorrhages recurred later and required a second treatment to produce definitive regular menstrual periods. The case cited for this group was a woman of 31 years with biopsy findings revealing a metropathy with enormous proliferation. The hemorrhage ceased after 175 mgm. of testosterone were administered; however, the next period was again hemorrhagic, and 200 mgm. of testosterone were administered in the interval; this resulted in two subsequent normal menstruations. The next period again exhibited bleeding which lasted 12 days; 75 mgm. administered during this succeeding interval resulted in a less abundant period of bleeding, and 75 mgm. administered during each of the two succeeding intervals finally achieved normal menstruation lasting for the succeeding 8 months of observation.

JOHN W. BRENNAN, M.D.

Triffat, P., and Burthiault, R.: Pelviparietal Phlegmon. A Special Type of Phlegmon of the Broad Ligament (Le phlegmon pelvi-pariétal, forme particulière des phlegmons du ligament large). *Rev. fr. gyn. obst.*, 1945, 40: 368.

The authors define a special type of phlegmon as pelviparietal phlegmon (phlegmon of the broad ligament).

The authors define a special type of pelvic phlegmon as pelviparietal phlegmon of the base of the broad ligament. It is located near the sciatic spine and is adherent to the pelvic wall. It is distinguished from phlegmon of the hypogastric sheath or of the base of the broad ligament by the fact that it is separated from the cervix uteri by a groove. This type of phlegmon has been described earlier in the literature but not identified as a special type. It is frequently discovered at vaginal examination following persistent temperature after delivery or abortion. In palpation for diagnosis after delivery or abortion, alternately. The cervix and uterus may be in normal or abnormal position and also the cul-de-sacs may appear normal, but exploration of the pelvic walls will reveal the phlegmon as a hard, slightly tender mass plastered against the pelvic wall. Its exact position can be demonstrated by a film centered on the lateral wall of the pelvis on the involved side, the anterior and inferior limits of the lesion being defined with the aid of two fingers in the vagina which have been rendered visible by the insertion of lead wire under the finger nails. The parietal mass may vary in size, shape, sensibility, and consistency, but it is always separated from the cervix uteri by a groove.

The symptoms may be absent, mild or severe, according to whether the phlegmon is subcutaneous or deep.

The symptoms may be absent, mild, moderate, or severe, according to whether one has to deal with an adenomyomatous form, a pyochemic form, or a form of venous involvement with suppuration. There are also early forms, developing on the second or third day after delivery or abortion, and late forms, appearing after 15 days. The lesions may be large, bilateral, or of mixed type. The lesions may be differentiated from oophoritis, and must be very different from the levator ani, and must be distinguished due to cervical pathology or endometritis. Although the prognosis is good, and complete retrogression the rule, recovery is usually slow, taking from 15 days to 3 weeks or more. The mass grows progressively softer, the groove disappears, and healing is complete. In some instances a small nodule before final healing. In other cases the small rounded lesion undergoes elongation into a small structure before it disappears. Possible complications include pulmonary symptoms and plebitis of the lower extremities. In the suppurative type of uterovaginal phlebitis, pulmonary infarct, lung abscess, or purulent pleurisy may ensue with death.

The authors have observed 33 cases over a period of 13 years, including 21 mild cases of adenomyomatous form, 9 cases with signs of venous involvement such as pulmonary infarct or phlebitis of the lower limbs, and 3 cases of suppurative uterovaginal phlebitis.

Because of the possible venous involvement in the pelvic parietal region, patients should not be per-

which may prove to be helpful in diagnosing these neoplasms and in following up their treatment.

EDWARD L. CORNELL, M.D.

MISCELLANEOUS

Lintgen, C., and Herbut, P. A.: Clinicopathological Study of 100 Female Urethras. *J. Urol., Balt.*, 55: 298.

Women with recurring attacks of frequency of urination and dysuria and usually without pathological evidence in the urine have in the past been subjected to complete urological and gynecological studies, but no satisfactory answer to the problem was obtained. The authors have undertaken a study to determine, if possible, what type of pathological change may be found in the routine female urethra that could possibly be an etiological factor in the production of these frequently unexplained urinary symptoms. They also attempted to determine the presence or absence of a prostatic gland in the female.

The entire urethra, bladder, and vagina were removed together from 100 consecutive cadavers. Eighty-six specimens were from adults and 14 from infants, 3 of whom were premature. The urethra was measured both for circumference and length prior to fixation. Following fixation, sections were made for microscopic study as follows: cross sections of the entire urethra in 24 cases; longitudinal sections of the entire urethra in 36 cases; and longitudinal sections of the posterior half of the urethra both in the midline and immediately lateral to the midline in 40 cases. In addition, the prostate and posterior urethra of 16 newly born, full term, and premature male infants were sectioned. Also, to compare the size of the posterior male urethra with that of the entire female urethra, measurements were taken of the prostatic urethra in 40 men who showed no hypertrophy of the prostate.

The belief of most embryologists that the female urethra is the homologue of the prostatic urethra of the male is supported by this study. The measurements of the entire female urethra and of the prostatic urethra of the male are strikingly similar. There is less agreement among anatomists regarding the presence or absence of glands in the posterior female urethra, and still less agreement as to whether or not these glands, if present, are homologues of the prostatic gland in the male. This study revealed glands present in every case in the anterior urethra and in 65 per cent of the posterior female urethras. These glands resembled microscopically some of the glands seen in the prostates of newly born and premature male infants.

None of the female urethras showed evidence of obstruction, but 76 per cent showed inflammatory reaction histologically. This reaction was confined most frequently to the mucosa and the submucosa. Nevertheless, this inflammation was present in 65.7 per cent of the cases without posterior urethral glands as compared with 56.9 per cent of the cases with glands.

Twenty-nine of the 76 patients showing inflammation had been catheterized before death, but the ratio between those having posterior glands and those having no glands in this group was about equal.

The cervixes were examined in all cases and showed no grossly apparent infection. Also, urethral inflammation was found in 4 of 15 full term female infants in whom cervical inflammation would be most unlikely.

The authors conclude, therefore, that the cause or causes of the urethral inflammations were not apparent. Posterior urethral glands, previous catheterization, or cervical inflammation did not appear to be a contributing factor. L. JAMES TAYLOR, M.D.

Beato, V.: Functional Uterine Hemorrhages and Their Treatment with Testosterone. (*Las hemorragias uterinas funcionales y su tratamiento por la testosterona*). *Rev. espan. obst.*, 1946, 3: 39.

In a previous communication (*Toko-Ginec. Proc.*, 1944, p. 465) the author discusses his experiences with testosterone in the case of myoma with bleeding, and claims to have preserved the reproductive capacity of many women, still young, by not subjecting them to hysterectomy or roentgen castration. He also includes cases of menorrhagia, metrorrhagia, and hemorrhage due to metropathy. He rejects the idea of treating the juvenile type of hemorrhage with testosterone because in young patients the possibility of a serious lesion in the tissues of the ovary has not been entirely disproved. Also in the mature woman he has resorted to the use of testosterone only exceptionally—in instances in which for some reason or another such treatment has been considered justifiable. Every day, however, more ample use is being made of this preparation in the functional type of hemorrhage which so often is observed to dominate the years of the climacterium and which is manifested principally in the guise of menorrhagias and metrorrhagias.

This hormone has been given by the author in a large number of cases of this nature; however, only 18 cases are the basis of this report. In these cases there has been a sufficient period of control to justify the author's speaking of the results of the treatment. In the majority of these cases the diagnosis was confirmed by histopathological examination of the endometrium, the specimen for study being procured by means of the streak curettement, or microcurettement (*Sirichabrasio* in German) before initiation of the treatment. In some instances also a biopsy was made after the treatment had been completed in an effort to demonstrate the changes in the endometrium as the result of the action of the testosterone and to seek the cause of the inhibitory effects on the hemorrhagic condition. These studies will be reported in a subsequent communication.

In 16 of the 18 patients the treatment was a complete success and in 2 a complete failure. Two possibilities are suggested as the reason for these failures: (1) the patients were among the early cases treated and the doses might have been too

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Kupperman, H. S., and Greenblatt, R. B.: The 2 Hour Pregnancy Test. *South. M. J.*, 1916, 39: 158.

A brief history of the tests employed to shorten the time necessary to make a diagnosis of pregnancy with no apparent sacrifice in accuracy is given. Utilizing the hyperemic effect of urinary gonadotropins upon the ovary, the authors have devised a pregnancy test with immature female rats which shortens the time necessary for completion of the test to 2 hours. Two cubic centimeters of unconcentrated urine are injected intraperitoneally into the female rats weighing between 30 and 80 gm. and the animals are then sacrificed by ether asphyxiation in 2 hours. Hyperemia of the ovary and the ovarian capsule is indicative of a positive reaction. The accuracy of the test proved to be 99.5 per cent in a total of 752 tests performed on 1,346 rats. These figures exclude observations on 18 ectopic pregnancies in which a correct diagnosis was obtained in 83.3 per cent. Comparison on 18 rat test with the Friedman test in a series of 251 cases showed the rat test to be 100 per cent accurate in this series as compared to 97.3 per cent accuracy with the rabbit procedure.

Immature hamsters and adult female mice were found to be suitable for this type of test, provided the animals were sacrificed in 15 or more hours. Neither guinea pigs nor immature mice were adaptable to the test.

Observations on the hormone responsible for the positive end-point indicated that this reaction is due to luteinizing or lutetotropic activity of the administered urine, and in the hands of these investigators, the normal menstrual cycle produced no false positive results. Among the emphasized advantages of this particular test are its accuracy, simplicity, availability of the test animal, and the short time required.

For, M. J., and Bortin, M. M.: Rubella in Pregnancy. *J. Am. Med. Ass.*, 1946, 130: 566.

This investigation of congenital malformations of the newborn of mothers who have had rubella during pregnancy is particularly worthy of note because it offers a more favorable prognosis for the infant than appeared justified from previous reports. The survey of the 3 year period reports rubella. Of this total 581 cases occurred from 1942 to 1944 152 or approximately 26 per cent of these married women. Eleven were pregnant at the time they had rubella. In 5 the disease occurred during the first 4 months of pregnancy, in 4 between the second and fourth months, and in 1 in the ninth month.

Of these 11 patients only 1 revealed a pathological course. This patient had rubella in the first month of pregnancy. The fetus was delivered, stillborn and hydrocephalic, 2 months before the expected date of confinement.

Others, in previous reports, have noted many congenital anomalies of infants born to mothers who have had rubella during pregnancy. Cataracts, heart disease, deaf-mutism, microcephaly, microphthalmus, atresia of the biliary ducts, and renal glomerulosclerosis have been reported. It has even been suggested by several that if a woman contracts rubella, a therapeutic abortion is indicated. These previous correlations and conclusions, however, have been based upon individual records, having rubella during pregnancy whose offspring had no congenital defects.

The present report does not justify the termination of pregnancy because of rubella. However, it does indicate the possibility of some relationship between congenital anomalies and this otherwise innocuous disease.

Waaler, E.: Acute Anterior Poliomyelitis Complicating Pregnancy. *Acta. med. scand.*, 1946, 143: 209.

The author poses a series of questions about acute anterior poliomyelitis complicating pregnancy. Does it run a more serious course in pregnancy? Does disease have any effect in pregnancy? Does the frequency of the disease complicating pregnancy? Does it have any effect on the child or does intrauterine infection occur?

The author has collected 8 cases, in 2 of which the mother died and was examined at autopsy. He also reports on 25 cases found in the literature. He also that from his small series and the few cases reported in the literature, it is difficult to ascertain with great accuracy the answer to the stated questions.

The mortality of the 33 cases in the two series used was 8, or 24 per cent, whereas the general average is between 10 and 20 per cent. It may be assumed from this that the mortality is higher in pregnancy, but the author points out that only the more serious cases may have been reported. Also, among the cases occurring at Bergen in 1941, 1 of 7 pregnant women died and 4 of 16 nonpregnant women died. As to the occurrence of the disease in the various months of pregnancy and its relative severity, the author states the following: 3 cases occurred in the first 2 months, 10 in the third and fourth months, 5 in the fifth and sixth months, 9 in the seventh and eighth months, and 6 in the ninth month. The deaths followed a different pattern, none occurring in the first 4 months, 1 in the fifth and sixth months, 6 deaths occurring in the seventh and eighth months, and 3 in the ninth month. The author states that it

mitted to get up too soon. Bed rest and the application of ice to the abdomen are recommended for all cases. In the milder types, the administration of sulfonamides may prove sufficient. In moderately severe cases the authors recommend a vaccine-containing streptococci, staphylococci, and enterococci. This is injected daily or every other day, beginning with a dose of $\frac{1}{4}$ c.c. and rapidly increasing it to 2 c.c. This vaccino-therapy is continued as long as the fever persists. In the most severe pyohemic cases, good results may be obtained by the intravenous drop infusion of alcoholized glucose serum.

EDITH SCHLANTZ MOORE.

Perelra, A. De S.: Abdominopelvic Sympathectomy for Relief of Pain of Cancer of the Cervix. *Arch. Surg.*, 1946, 52: 123.

The relief of pain secondary to pelvic carcinoma by surgical therapy was first attempted by Jaboulay in 1889. Leriche, in 1921, introduced periaarterial sympathectomy of the hypogastric arteries, and Cotte in 1925 showed that pelvic pain may be relieved by interruption of the hypogastric plexus. Further studies of Leriche, Fontaine, Herrmann, Greenhill, Wetherell, Atlee, Fulcer, Cutler, and VerBruggen are briefly but adequately discussed in this article. Sousa started this study to clarify two problems:

1. The effect of abdominopelvic sympathectomy.
2. The merit of bilateral ligation of the hypogastric arteries.

The ligation was done to avoid the danger of hemorrhage from the ulcerated carcinoma of the cervix following sympathectomy which is known to increase the collateral circulation of the uterus after ligation of the hypogastric arteries. Different types of abdominopelvic sympathectomy were performed in order to determine their comparative values in the treatment of pain in inoperable cancer of the cervix uteri.

An attempt was also made to determine whether abdominopelvic sympathectomy "must or must not be followed by adequate physical therapy (radium and roentgen rays)."

The problem is complicated by the fact that the uterus derives its sympathetic nerve supply mainly from the hypogastric plexus, and secondarily from nerve fibers which accompany the hypogastric ves-

sels. Afferent sensory fibers conducting painful sensations from the uterus along the hypogastric and aortic plexus and through the lumbar sympathetic chains join to reach the spinal cord through the eleventh and twelfth thoracic nerves. The sensory fibers that accompany the hypogastric and common iliac vessels probably run through the lumbar sympathetic chain before they arrive at the spinal cord.

The technique used consisted of opening the abdomen by a median subumbilical incision. Careful and complete examination of the pelvis determines the extent of invasion of the tumor. Abdominopelvic sympathectomy to relieve pain is planned according to the finding in each case. The peritoneum is incised beginning just below the inferior mesenteric artery and down beyond the bifurcation of the aorta, with a Y-shaped incision over the course of the right and left common iliac arteries to a point beyond the origin of the hypogastric arteries. Then, the hypogastric plexus, the lower part of the aortic plexus, and the lumbar sympathetic chains may be resected. This operation completely interrupts the hypogastric afferent pathways from the pelvic organs; but it is also necessary to interrupt the afferent pathways that follow the vessels, particularly the arteries. For this reason, periaarterial sympathectomy of the common iliac arteries and sympathectomy of the inferior mesenteric artery are required to complete the interruption of the afferent pathways from the pelvis.

In all cases, after abdominopelvic sympathectomy, ligation of the hypogastric arteries was always done.

A total of 14 patients comprise the author's material. In 7 the operation was limited to resection of the hypogastric plexus. In the last 7, the operation was extended to interrupt additional sympathetic pathways. None of the patients died from hemorrhage. The results were improved when the radium was applied during the period of increased blood supply caused by the vasodilatation following the sympathetic operation. Visceral sympathetic pain was absent as long as the carcinoma remained within the anesthetized area, but when the carcinoma progressed and invaded the lumbosacral plexus, pain which radiated down the lower extremities manifested itself.

SAMUEL J. FOGELSON, M.D.

the uterus as in the Kristeller maneuver, thus delivering the arms and shoulders. The lordosis is now exaggerated by carrying the buttocks over the abdomen of the mother; the chin and then the mouth appear and, finally, the head is delivered in deflexion.

In 26 patients with pelvic presentation Bracht's maneuver was employed. In 1 case there were twins and the second child was delivered in cephalic presentation. Sixteen of these mothers were primiparas, 3 being 32, 36, and 37 years of age, respectively; 2 were secundiparas, and the remaining 8 were multiparas. Twenty of the deliveries were at term and 6 took place when the pregnancy was between 8 and 8½ months. Nine of the infants weighed from 2,000 to 3,000 gm.; 14 weighed from 3,000 to 4,000 gm., and 1 weighed 4,340 gm. Twenty-three of the deliveries were from incomplete pelves and the remaining 3 from complete pelves.

In 23 of the entire 26 mothers treated by Bracht's maneuver, the labor was perfectly successful (88.4 per cent). In 1 of the 3 women whose labor course was considered a partial failure, one arm had to be brought down manually; however the remainder of the course was perfectly normal, giving a true percentage of success of 92. Of the remaining 2 unsuccessful deliveries in which the child had to be extracted, one infant proved to be a mongoloid with marked edematous swelling about the neck and throat; no explanation—except, possibly, inexperience of the operators—could be adduced for the failure in the remaining case. In 1 instance proclivencia of the cord took place; however, it was not interfered with, the delivery of the child taking place almost immediately, and at no time did the pulsation of the cord indicate any inconvenience on the part of the fetus.

The delivery of the head deflexion and the inability of the operator to guard the perineum personally seems to be a disadvantage of the Mariceau maneuver, and in the author's material this has resulted in a rather high percentage of perineal ruptures (18 per cent in primiparas and 19 per cent in the entire material). The author believes this should be countered by limiting as much as possible the expulsive (Kristeller) pressure exercised suprapubically by the assistant on the after coming head and by extending the use of episiotomy. However, it is not to be assumed that the deflected position of the head during delivery is more than normal. It is considered that in the Mariceau maneuver the flexion of the head is exaggerated, but it is rather a relative condition, incidental to the exaggerated lordosis of the infant's body. The author is unable to substantiate this opinion, however, and suggests that x-ray studies of the passage of the fetal head through the maternal pelvis be made.

A lengthy theoretical discussion of the entire process of labor in breech presentation, including the author's ideas as to why the Bracht maneuver seemed to be somewhat more successful in incomplete than in complete pelvic mechanisms, could not be abstracted.

JOHN W. BRENNAN, M.D.

Mitchell, R. M.: Forceps for Delivery—Their Use and Abuse. *Surg. Clin. N. America*, 1945, 25: 1436.

This article presents a review on the proper use of forceps, with a warning that misuse of the instrument will lead to many fetal and maternal injuries. The first portion of the article outlines the fundamental principles of obstetric forceps, which are:—

- (1) Knowledge of the instrument
- (2) Function of the forceps—this is divided into the four major functions of the forceps
 - a. Traction
 - b. Rotation
 - c. Leverage
 - d. Compression
- (3) Classical applications
 - a. Pelvic
 - b. Cephalic
 - c. Cephalopelvic
- (4) Principles of application
 - a. The law of the forceps
 - b. The rule of the forceps
- (5) Indications for the use of forceps
 - a. Maternal
 1. Insufficiency of the powers
 2. Rigid perineum
 3. Large baby
 4. Inability to bear down
 5. Maternal exhaustion
 6. Previous cesarean section
 7. Toxemia of pregnancy
 8. Pulmonary disease
 9. Cardiac disease
 10. Renal disease
 11. Premature separation of placenta
 12. Marginal placenta previa
 - b. Fetal
 1. Intrauterine asphyxia
 2. Abnormal presentation
 3. Prematurity
 4. Prolapsed cord
- (6) Conditions for the use of forceps
 - a. Surgical asepsis
 - b. Empty bladder and rectum
 - c. Knowledge of fetal position
 - d. Complete effacement and dilatation of cervix
 - e. Ruptured membranes
 - f. Absence of disproportion
 - g. Live baby
 - h. Station of the baby

The remainder of the article is devoted to detailed description of the various forceps operations in an outline form in which all the "do's" and "don't's" are carefully emphasized.

JAMES F. DONNELLY, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Douglas, R. G., and Davis, I. F.: Puerperal Infection. *Am. J. Obst.*, 1946, 51: 352.

Evidence has been presented indicating a decreased mortality from puerperal infection in the

would seem that the prognosis for mothers contracting this disease in the last months of pregnancy is bad.

The author believes that, at least from his series of cases, poliomyelitis does not cause, nor increase the frequency of, complications of pregnancy or labor.

In comparing his series with 2 other reported series, the author believes that the frequency of the disease is greater in pregnant women, but states conservatively that the series were small.

As to the action of poliomyelitis on the fetus and child, the author reports that all of the live infants showed no evidence of the disease and all were well at the end of 3 years. Microscopic study of sections of the nervous system of the 2 women who died revealed no evidence of transmission to the fetus.

BYFORD F. HESKETT, M.D.

Dana, E. S.: Premature Delivery; Causes and Results. *Am. J. Obst.*, 1946, 51: 329.

A series of 941 cases of premature delivery at the author's clinic was studied. The incidence of prematurity was found to be 2.95 per cent. The causes of premature labor and delivery were classified as maternal, fetal, and placental. The obstetric factors in premature deliveries were discussed. The incidence of operative delivery in this group was 27.9 per cent. The gross infantile mortality was 33.3 per cent. The corrected infantile mortality was 18.8 per cent. Both gross and corrected infantile mortality rates have shown a steady decline in the past 10 years.

It was concluded that the causes of premature delivery are, in many cases, beyond the control of the obstetrician. His role in the prevention of prematurity consists in the control of syphilis and febrile diseases, and in continued research on the toxemias of pregnancy.

The obstetric management at the time of delivery was found to affect the infantile mortality. It was shown that spontaneous or low forceps deliveries were the procedure of choice. The use of episiotomy was found to be of value. Morphine as an analgesic agent was contraindicated. The availability of prompt oxygen therapy and expert pediatric care is of prime importance. EDWARD L. CORNELL, M.D.

Burthault, R., and Sournia, J.: Genital Infarcts after Abortion (Les infarctus genitaux post-abortum). *Lyon chir.*, 1945, 40: 347.

Infarction of the uterus and/or the ovary coinciding with an abortion is a rare occurrence; only 55 cases are on record in the entire literature.

As to the etiology, opinions differ, and it is difficult to decide if this complication occurs more often in spontaneous or in induced abortion. Although genital infarcts have been observed in the absence of pregnancy, in most instances criminal manipulations have been either proved or suspected. Especially the intrauterine injection of soap solution seems to play a fatal role in many cases.

The symptoms are those of an acute generalized peritonitis. The uterus is much larger than would correspond to the stage of pregnancy; it is very hard and gives the impression of being wooden. A very important sign is the blue or blackish discoloration of the cervix, either *in toto* or in part. As this sign has often been observed in the early stages, the authors stress that the vaginal examination with the speculum should never be omitted. Only an early diagnosis can save the life of the patient, and even gangrene of the cervix may be found at a time when the corpus is still intact.

The treatment is immediate hysterectomy. The prognosis is very serious; of the 55 cases on record, 32 ended fatally, usually because of shock or progressive intoxication.

The authors give 2 case histories of infarction after abortion in the fourth month of pregnancy. Both ended fatally. WERNER M. SOLMITZ, M.D.

LABOR AND ITS COMPLICATIONS

Baldi, E. M.: Our Experience with Bracht's Maneuver in Delivery in Cases of Pelvic Presentation (Nuestra experiencia con la maniobra de Bracht en la atención del parto en presentación pélvica). *An. Inst. maternidad*, 1944, 6: 29.

Of a series of 51 cases of delivery with pelvic presentation Baldi found in 86.3 per cent that Bracht's maneuver was effective. The simplicity as well as the freedom from infection of this operation, as there is no need to introduce the hand into the birth canal, leads the author to recommend this procedure for tocological practice. WILLIAM E. RUCKERTS, M.D.

Nieva, M. R.: The Bracht Maneuver in the Delivery of Pelvic Presentations (La maniobra de Bracht en la atención del parto en presentación pélvica). *An. Ateneo Inst. maternidad*, 1945, p. 101.

Bracht maintains that the classic method of delivering the child in pelvic presentation, instead of favoring, actually perturbs the physiologic mechanism, if one accepts the interpretation of Sellheim. This author taught that, once the buttocks had been born, the fetus rotates so as to place the dorsum toward the front, which causes the shoulders to become engaged in the transverse diameter of the pelvis. The pelvic pole is lifted anteriorly, which produces a lordosis of the trunk and thus executes a motion of rotation about the symphysis pubis. This movement, however, promptly terminates as the force of gravity causes the body of the infant to fall down between the thighs of the parturient woman.

In the Bracht method this opposition of the force of gravity to the movement of rotation about the symphysis is opposed manually. This is accomplished in the following manner:

After expulsion of the pelvic pole the accoucheur waits until the points of the scapulae appear and then grasps the buttocks and thighs with both hands and lifts the fetus without exerting traction. At the same moment an assistant exerts pressure on the body of

the uterus as in the Kristeller maneuver, thus delivering the arms and shoulders. The lordosis is now exaggerated by carrying the buttocks over the abdomen of the mother; the chin and then the mouth appear and, finally, the head is delivered in deflexion.

In 26 patients with pelvic presentation Bracht's maneuver was employed. In 1 case there were twins and the second child was delivered in cephalic presentation. Sixteen of these mothers were primiparas, 3 being 32, 36, and 37 years of age, respectively; 2 were secundiparas, and the remaining 8 were multiparas. Twenty of the deliveries were at term and 6 took place when the pregnancy was between 8 and 8½ months. Nine of the infants weighed from 2,000 to 3,000 gm.; 14 weighed from 3,000 to 4,000 gm., and 1 weighed 4,340 gm. Twenty-three of the deliveries were from incomplete pelvises and the remaining 3 from complete pelvises.

In 23 of the entire 26 mothers treated by Bracht's maneuver, the labor was perfectly successful (88.4 per cent). In 1 of the 3 women whose labor course was considered a partial failure, one arm had to be brought down manually; however the remainder of the course was perfectly normal, giving a true percentage of success of 92. Of the remaining 2 unsuccessful deliveries in which the child had to be extracted, one infant proved to be a mongoloid with marked edematous swelling about the neck and throat; no explanation—except, possibly, interference of the operators—could be adduced for the failure in the remaining case. In 1 instance proclivity of the cord took place; however, it was not interfered with, the delivery of the child taking place almost immediately, and at no time did the pulsation of the cord indicate any inconvenience on the part of the fetus.

The delivery of the head deflexion and the inability of the operator to guard the perineum personally seems to be a disadvantage of the Mariceau maneuver, and in the author's material this has resulted in a rather high percentage of perineal ruptures (18 per cent in primiparas and 19 per cent in the entire material). The author believes this should be counteracted by limiting as much as possible the expulsive pressure exercised suprapubically by the assistant on the after coming head and by extending the use of episiotomy. However, it is not to be assumed that the deflected position of the head during the Mariceau maneuver is not to be exaggerated, but it is rather a relative condition, incidental to the exaggerated lordosis of the head in body. The author is unable to substantiate this opinion, however, and suggests that x-ray studies of the passage of the fetal head through the maternal pelvis be made.

A lengthy theoretical discussion of the entire process of labor in breech presentation, including the author's ideas as to why the Bracht maneuver seemed to be somewhat more successful in incomplete than in complete pelvic mechanisms, could not be abstracted.

JOHN W. BRENNAN, M.D.

Mitchell, R. M.: Forceps for Delivery—Their Use and Abuse. *Surg. Clin. N. America*, 1945, 25: 1436.

This article presents a review on the proper use of forceps, with a warning that misuse of the instrument will lead to many fetal and maternal injuries. The first portion of the article outlines the fundamental principles of obstetric forceps, which are:

- (1) Knowledge of the instrument into the four major functions of the forceps
 - a. Traction
 - b. Rotation
 - c. Leverage
 - d. Compression
- (2) Classical applications
 - a. Pelvic
 - b. Cephalic
 - c. Cephalopelvic
- (3) Principles of application
 - a. The law of the forceps
 - b. The rule of the forceps
- (4) Indications for the use of forceps
 - a. Maternal
 1. Insufficiency of the powers
 2. Rigid perineum
 3. Large baby
 4. Inability to bear down
 5. Maternal exhaustion
 6. Previous cesarean section
 7. Toxemia of pregnancy
 8. Pulmonary disease
 9. Cardiac disease
 10. Renal disease
 11. Premature separation of placenta
 12. Marginal placenta previa
 - b. Fetal
 1. Intrauterine asphyxia
 2. Abnormal presentation
 3. Prematurity
 4. Prolapsed cord
- (5) Conditions for the use of forceps
 - a. Surgical asepsis
 - b. Empty bladder and rectum
 - c. Knowledge of fetal position
 - d. Complete effacement and dilatation of cervix
 - e. Ruptured membranes
 - f. Absence of disproportion
 - g. Live baby
 - h. Station of the baby

The remainder of the article is devoted to detailed description of the various forceps operations in an outline form in which all the "do's" and "don't's" are carefully emphasized.

JAMES F. DONNELLY, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Douglas, R. G., and Davis, I. F.: Puerperal Infection. *Am. J. Obst.*, 1946, 51: 352.

Evidence has been presented indicating a decreased mortality from puerperal infection in the

United States, amounting to approximately 50 per cent during recent years, as compared to previous experience. However, in New York, these rates remain essentially the same, despite a decrease in the total maternal mortality during the past decade to one-third of the former rate. In the New York Lying-In Hospital both the incidence of puerperal infection and the mortality associated with this condition have shown a progressive and very significant decrease.

The bacteriologic data obtained from the study of 1,000 patients subjected to investigation is presented in tabular form. It indicates that the great majority of infections occurring during the puerperium and postabortal period are endogenous in origin, and caused for the most part by different groups of nonhemolytic streptococci.

An analysis of underlying conditions responsible for the development of infection, such as hemorrhage, anemia, prolonged labor, cesarean section, and other operative procedures, is shown graphically.

Prophylaxis of infection is shown to be far more important than the treatment of the disease once established. Measures aimed at the prevention of exogenous infections and their successful employment are illustrated. Prevention of endogenous infections is discussed in more detail, including methods of avoiding underlying causes as well as actual prevention of the invasion of organisms when unavoidable situations arise.

It is the authors opinion, based on experience but not proved conclusively, that sulfadiazine, given early during long labors and under certain other circumstances, will decrease the incidence of infection. Sulfadiazine or penicillin given early may be efficacious, while when given late in the course of the disease it may be relatively ineffective.

EDWARD L. CORNELL, M.D.

NEWBORN

Beck, A. C.: The Obstetrician's Responsibility for the Hazards of the First Few Days of Life, with Special Reference to Anoxia and Prematurity. *Am. J. Obst.*, 1936, 51: 173.

In the 5 year period from 1930 through 1934, 7,580 infants weighing 1,000 gm. or more were born at the Long Island College Hospital, Brooklyn, New York. Twelve, or 1 in 631, of the mothers died. During this period, 99, or 1.3 per cent, of the infants were born dead and 101, or 1.33 per cent, died while in the hospital. Congenital anomalies were responsible for 32.6 per cent of 101 neonatal deaths. Nine and nine-tenths per cent were due to infection. Brain hemorrhage was demonstrated in 14.8 per cent, while the remainder of the dead infants, or 41.5 per cent, showed nothing more than congenital atelectasis when autopsy was permitted. In the last group of infants, respiratory symptoms had almost invariably been present, and most of the deaths in this group were preceded by periods of intermittent cyanosis. These respiratory symptoms were the

same as those which are present when tentorial tears and injuries of the brain are demonstrable at autopsy; therefore, the brain has been injured also.

The effect of a diminished oxygen supply, both in the mother and in the fetus, is discussed. The mortality from breech delivery of the infants weighing from 1,500 to 2,000 gm. was 50 per cent, or almost two and one-half times the mortality of the series of infants of the same weight. It was only among the larger infants, which weighed more than 2,000 gm., that the mortality of breech delivery approached that of the series. Spontaneous delivery with episiotomy done under local anesthesia was shown to be the safest method of delivery for the premature infant.

If the 9 cases in which cesarean section was done for placenta previa and the 2 in which the child died as a result of congenital anomalies are deducted from the 39 cases of cesarean sections, there remain 13 cases undergoing operation with 2 deaths, a premature infant mortality of 7 per cent. Therefore, cesarean section is at times a valuable method of delivery.

EDWARD L. CORNELL, M.D.

MISCELLANEOUS

Thomas, R. C.: Results In 18,600 Booked Deliveries. *Lancet*, Lond., 1946, 1: 101.

The plan under which the Borough of Croydon's obstetric service operates is discussed by the author and is offered as a model after which similar services might be instituted in other boroughs comprising a population up to 250,000 persons.

The entire service is supervised by a single obstetrician whose duty it is to integrate the work of all midwives and obstetricians in providing ideal antenatal, natal, and postnatal care for all. Home as well as hospital deliveries are included in the scope of the plan, and complicated home deliveries are aided by the work of a so-called "emergency flying squad" which renders resuscitative measures and provides for immediate hospitalization.

A statistical analysis of 18,632 booked deliveries after the twenty-eighth week under the above plan encompassing an 8 year period is given. Altogether, 18,822 infants, including 190 sets of twins were delivered. Three mothers died undelivered and 14 died after delivery. The deaths are classified as follows: directly due to pregnancy, 0.53; associated with pregnancy, 0.37; and a total (all causes) of 0.9 per 1,000 total births. The stillbirth rate was 2.1 per 1,000 total births, and the infant death rate, 15.5 per 1,000 live births. JAMES F. DONNELLY, M.D.

Goodwin, M. S., and Moore, J. E.: Prenatal Syphilis. *J. Am. M. Ass.*, 1946, 130: 685.

The authors have analyzed a series of 57 pregnant women with early syphilis treated with penicillin (31 from their own clinic and 26 previously reported by Ingraham et al.). Patients with early syphilis were purposely selected to test the efficacy of penicillin in the prevention of infantile congenital syphilis.

in that group of cases in which the probability of infection of the fetus was greatest. Fourteen mothers were treated before the sixteenth week of gestation; treatment was given to 31 between the sixteenth and thirty-second week, and the duration of pregnancy in 12 was 32 weeks or longer when treatment was begun.

Of the 57 patients, only 2 had received previous antisyphilitic treatment, and in both instances the circumstances of the previous treatment was such that they could be considered cases of early syphilis. One was apparently reinfected during pregnancy following a symptom free, seronegative period, and the other was a reinfection of cured congenital syphilis.

The total dosage range of the single courses of treatment in both groups was comparable, the majority of the patients having received from 1.2 to 2.4 million units of penicillin. Of the 57 patients, 5 were re-treated during pregnancy because of serologic relapse. In each of these 5 instances, the babies were born alive and apparently normal. Two mothers had a clinical relapse—one, whose infant was the only one in the series to develop congenital syphilis at term, and the other 4 weeks postpartum. The serologic response in general tended to revert toward

negativity at the same rate in pregnancy as in males or nonpregnant females.

Of the 61 babies delivered from these 57 mothers, only 1 developed congenital syphilis during the period of observation; 49 of the remainder were followed up for more than 2 months, and 18 of these who were seropositive at birth had become seronegative.

One hundred and fifty cases were given intensive arsenotherapy with a resultant failure rate of 15 per cent while of the 60 infants delivered of the 57 women treated with penicillin only 1 child was syphilitic—a failure rate of 1.6 per cent. Furthermore, with penicillin the results were equally good no matter what the duration of pregnancy at the time treatment was begun, which contrasts to a failure rate of from 5 to 50 per cent from metal chemotherapy, according to the stage of pregnancy when therapy was instituted.

Statistically, it did not appear that penicillin was directly or indirectly responsible for abortion.

On the basis of this report, the authors recommend that in syphilitic pregnant females, penicillin be used routinely for the prevention of neonatal syphilis, and that other methods of therapy be abandoned.

JAMES F. DONNELLY, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Kittredge, W. E., and Brown, H. G.: *The Present Status of Unilateral Renal Hypertension. J. Urol., Balt., 1946, 55: 213.*

Following Goldblatt's work on renal ischemia as a factor in producing hypertension, attention was directed to unilateral renal disease as a cause of hypertension. Further experimental and clinical research suggested that the development of hypertension in these cases was of humoral rather than of neurogenic origin. However, the exact etiological basis for unilateral renal hypertension is still speculative.

Search for a characteristic microscopic appearance of the kidney pathology in cases of unilateral renal hypertension has been fruitless. It is to be noted that the Goldblatt kidney does not show arteriosclerotic changes until renal insufficiency has developed. Furthermore, even when hypertension is produced by a unilateral renal lesion, it can cause irreversible vascular changes in the opposite kidney, which changes in themselves are capable of continuing the hypertensive disease.

The clinical application of much of the research findings to the treatment of unilateral renal hypertension in the human subject would be facilitated if there were a clinical picture characteristic of unilateral renal hypertension. In an effort to bridge this gap, the following suggestions have been advanced:

1. Ravitch suggested that certain anatomic peculiarities of the kidney be used, e.g., the intra-renal type of pelvis when influenced by even mild pathological conditions might result in hypertension by constricting the renal artery. This has not been confirmed by other investigators.

2. Flocks believes the most important consideration in selecting cases for nephrectomy is relative renal ischemia in the kidney in question; this is recognizable by a comparison of the total renal mass, seen in the roentgenogram, with the differential phthalein function of the kidney. Reduction in renal function without commensurate reduction in the cortical renal mass is considered evidence of relative ischemia and is thought to represent the most favorable case for nephrectomy. However, in experimental unilateral renal hypertension, there may not be any demonstrable variation from the normal anatomic structure or function of the kidney.

In an evaluation of the end results of nephrectomies done to relieve unilateral renal hypertension, among the factors to be considered is a realization that:

1. An accurate evaluation of results is impossible before a year has elapsed after operation, because

- a. The temporary fall in blood pressure following surgery may be due to enforced bed rest

and change in the mode of living, or even to the removal of toxicity in infected cases.

- b. This fall may last for months before hypertension recurs, although symptomatic relief may continue. In some cases, as much as a year elapsed before hypertension reappeared.

2. No permanent change in the blood pressure can be reasonably expected to follow the removal of a functionless kidney, regardless of whether or not the diseased kidney was the original cause of the hypertension. In either case the presence of the hypertension may have caused irreversible arteriolar changes in the opposite kidney.

3. The incidence of hypertension in a series of patients with unilateral kidney disease is actually no greater than the incidence in any other group of patients of comparable age, chosen at random.

In a recapitulation by the authors, of Mayo Clinic experience, it was reported that the renal lesion most often associated with hypertension, which was most amenable to surgical treatment, was atrophic pyelonephritis. It was also noted that the severity of the atrophy was in direct proportion to the incidence of hypertension. The incidence of hypertension was low in pyelonephritis without atrophy and sclerosis. Acute cortical infections were seldom, if ever, the cause of hypertension. The next most common lesion associated with hypertension in the Mayo Clinic series was renal neoplasm, followed in order by renal lithiasis, hydronephrosis, tuberculosis, and polycystic kidneys. In cases of renal lithiasis, it was found that the role of infection was important, since hypertension occurred in 25 per cent of the cases in which infection was present, and in only 5.7 per cent of those in which there was no infection. The deciding factor, however, was not the degree of infection but the presence of extensive vascular sclerosis and parenchymal atrophy. A followup study of the patients with hypertension who were operated on showed that hypertension was relieved in 70 per cent of the cases of pyelonephritis, in 50 per cent of those with tuberculosis, and in 25 per cent of those with renal stone, hydronephrosis, or tumor.

The point is also made that previous conservative operations on the kidney or actual renal trauma may cause unilateral hypertension in some cases; if hypertension should develop later, unexplained on any other basis, nephrectomy is probably indicated.

In all the cases of unilateral renal hypertension treated by the authors at the Ochsner Clinic, it was their custom to do a unilateral splachnicectomy at the time nephrectomy was done, in order to have that much accomplished in the event that a bilateral splachnicectomy should be considered desirable later. Unilateral splachnicectomy does not produce a beneficial effect on hypertension, and therefore, does not influence whatever result is obtained from nephrectomy.

Included are 4 case reports by the authors, illustrative of some of the various considerations discussed.

EUGENE J. AUDI, M.D.

Burford, C. E.: Nephroptosis with Coexisting Lesions. *J. Urol.*, Balt., 1946, 55: 220.

The too obvious cause of disabling pain in several of the author's patients led to a reattempt at nephropexy with gratifying results, which seem both to revive and to place on a new basis this formerly discredited operation.

A new feature was the more exact diagnosis. The cystoscopic roentgenographic combination table makes it possible to secure pyeloureterograms in both recumbent and upright positions, and thereby visualize the cause of pain, and also visualize any destructive processes in cases of nephroptosis. The operative procedure corrected the difficulties encountered in obtaining proper drainage through the ureteropelvic juncture and a properly functioning ureter.

A brief presentation of the clinical picture of nephroptosis includes:

Causes. These are asthenia, debilitating diseases, childbirth, and trauma from falls or blows.

Symptoms. Usually the first is pain, coming on after the patient is tired or on the feet for long periods. The pain may be in the posterior fossa under the twelfth rib or on either side of the abdomen, radiating to the genitals and urethra. It is usually due to retention of only a few cubic centimeters of urine in the kidney pelvis. The second most common symptom and one which usually accompanies the first is nausea, with or without vomiting. Occasionally the patient merely complains of anorexia with consequent loss of weight.

Body build. Some marked cases of nephroptosis are found in obese patients; the majority of psoed kidneys, however, occur in thin patients who have lost weight and have relaxed abdominal walls.

Complications. Often the kidney is only a part of a splanchnoptosis, and if the position of the kidney and ureter causes urinary stasis with hydronephrosis, infection and stone formation frequently follow.

In arriving at a decision as to whether operative interference is indicated, it is not sufficient to say that there is a low or movable kidney. Kidneys which can be palpated at the level of the pelvic brim are often asymptomatic and function normally. A complete urological examination is necessary with careful interpretation of the findings before it can be decided that nephropexy will relieve the patient's symptoms and stop the destructive process in the kidney itself.

The cystoscopic examination must take note of any obstruction encountered in either ureter; aspiration of each ureteral catheter must be done after it has reached the kidney pelvis to determine the residual urine; a phthalein function test (intravenous) should be made; and the time of appearance of the drug from each kidney and the concentration

for at least 10 minutes should be noted. A flat plate of the abdomen is made to determine whether stones are present, and this is followed by bilateral pyelograms with the patient in the horizontal position and with the lungs in expiration. Overdistention of the pelvis, resulting in the production of colic, must be avoided. Another pyelogram is taken with the patient in a semisitting position and during held deep inspiration; this last film will visualize any kinks in the upper ureter, produced by the descent of the 2 kidneys, and any constrictions at the ureteropel junction.

If stones are found in the kidney or ureter, they are removed during operation for nephropexy. Chronic infection in the kidney pelvis is not considered a contraindication to operation. Stasis of urine and infection in the kidney pelvis may be cleared up in some instances only by nephropexy and the necessary plastic surgery on the kidney pelvis and ureter.

Generally, the operative technique of Kelly is followed, in addition to which the upper portion of the ureter is exposed and carefully freed from all adhesions and anomalous vessels which might interfere with free peristalsis. These bands or fibers may not appear to constrict, but may run parallel with the ureter as an integral part of its external structure. However, they rob the ureter of its elasticity and prevent proper peristalsis, and they must be dissected away. Most of the lesions which cause destructive hydronephrosis in cases of nephroptosis are located at the ureteropelvic juncture and are made worse by the kidney's low position which causes an increase in the angulation of the ureter at this point. The general rules formulated from the author's experience in attempting the plastic procedures necessary in each case, to secure good functional drainage, are: ablate excess pelvic tissue in a manner that will leave the ureter draining from the lowest portion. If there is a constriction or ring of fibrous tissue, a Y-plasty is done and splinted with an indwelling catheter. Small aberrant vessels, crossing the pelvis to the lower pole, are ligated and cut. If, on compression, these vessels appear to supply as much as one-third of the kidney, the ureter is reimplanted in the lowest portion of the pelvis, at a point where it will not be constricted, instead of sacrificing the circulation of the kidney.

If there is a stone in the kidney, it is removed through a pelvic incision or by nephrotomy and the kidney is drained through its substance rather than through the pelvis. An infected hydronephrosis is drained in the same manner.

The last step is the suturing of the kidney in a high yet natural position so that the ureter will be straight but not taut. In clean cases, medium sized silk is the suture of choice, while No. 1, 20 day catgut is used when infection is present. The capsule is left intact because it makes a firmer hold for the sutures and avoids the formation of a sclerosing shell to constrict the circulation at a later date. Kelly's three point stitch in the capsule has proved most

satisfactory, the upper suture being brought out and tied in the intercostal muscles between the eleventh and twelfth ribs. The other two are taken in the muscles and fascia in the back under the twelfth rib. Care must be taken not to rotate the kidney out of the plane of its normal position. Postoperatively, the patient is kept flat in bed for 2 weeks, then gradually allowed out of bed over a period of about 17 days. In the author's experience in more than 200 nephropexies, there has never been occasion to re-operate because of failure of kidney suspension. In about 6 cases, operated on later because of additional renal disease, all the previously suspended kidneys were found firmly fixed.

The conclusions reported are similar to those made when the author reported his first 48 cases in February, 1927, although much improvement has been made on the plastic procedures at the ureteropelvic junction.

EUGENE J. AUDR, M.D.

Dorman, H. N., and Fowler, H. A.: Hemangioma of the Kidney. *J. Urol.*, Balt., 1946, 55: 348.

A case of hemangioma of the kidney is reported with a review of the literature.

Hemangiomas are rarely encountered in the kidney. The number of cases so far recorded probably does not exceed 50, including both autopsy specimens and clinical cases. These tumors rarely attain a large size; they may be situated in any portion of the kidney. They are, however, usually small, and the tip of a papilla of the kidney is their favorite location.

In general, benign tumors of the kidney are asymptomatic, presenting symptoms due to pressure only when of unusual size. In contrast, hemangiomas and papillomas of the renal pelvis, both benign, produce symptoms—hematuria—at times so urgent as to demand prompt surgical interference as a life-saving measure. The hematuria, usually unaccompanied by severe subjective symptoms, is of sudden onset and commonly intermittent. The interval may vary from days to years. Further study reveals that the bleeding is unilateral. Pyelographic study is usually inconclusive. The only filling defect may be that of a large blood clot in the renal pelvis. The diagnosis is usually not made before operation, but after pathological study of the lesion.

The authors believe that the diagnosis of essential hematuria is meaningless and unsatisfactory in cases of intermittent hematuria which are unilateral in type and moderate in severity. Every such case if studied extensively enough will reveal some underlying pathological condition sufficient to explain the bleeding. If the urinary abnormalities associated with nephritis are absent, and if upon exhaustive study no probable cause is demonstrable, one should think of lesions of a renal papilla, the most serious of which is angiosarcoma.

In the majority of the cases nephrectomy has been performed as an emergency measure to save the patient's life. Bisection of the kidney for adequate exploration is only to be condemned because of the

high mortality and the resulting damage to the kidney structure and its functions. Nephrectomy should not be performed until conservative measures have been employed, such as the use of vitamin K, whole blood transfusion, and lavage of the renal pelvis with silver nitrate.

FREDERICK R. LIEBERTHAL, M.D.

Kretschmer, H. L.: Bilateral Primary Sarcoma of the Kidney. Report of a Case and Review of the Literature. *Q. Bull. Northurst. M. School*, 1945, 20: 77.

The author reviews the case of an individual who suffered a bilateral renal sarcoma, this being the thirty-ninth such case recorded in the literature.

The patient was a 56 year old white male who originally complained of lassitude, anorexia, and fatigue. The first physician called found a distinct pyuria. Intravenous pyelography revealed an afunctional left kidney; the remainder of the urinary tract was normal except for the spider web deformity of the right calyces, and the left renal pelvis showed evidence of obstruction with dilatation of the calyces. The last may have been due to a questionable shadow in the left ureteral region suggestive of calculus of the size of a wheat grain in the upper ureter. The prostatic secretion demonstrated a few pus cells and there was found a residual urine of 45 c.c. with a great amount of pus.

Cystoscopic examinations revealed a trabeculated bladder and the presence of a posterior commissure, along with a ureteral stricture on the left side which was finally traversed by a ureteral catheter. The urine from the right kidney was normal while that from the left contained pus and the escherichia coli.

Eighteen months later the patient complained of strangury, dysuria, dribbling, frequency, and nocturia. Renal function was markedly impaired, and after preparation the median commissure was resected. After operation the renal function was found to be unimproved with the nonprotein nitrogen at 200 mgm. per 100 c.c. the day before discharge. On this day neither kidney was palpable as compared to the findings when the patient was first seen, at which time the left kidney was palpable. This was believed to be due to hydronephrosis following the visualization of a shadow that was seen in the path of the upper left ureter and of a stricture of the same ureter, which was finally traversed with a ureteral catheter and dilated.

Five months after hospitalization the patient returned to the hospital complaining of weakness, anorexia, constipation, and loss of weight, but without symptoms. At this time both kidneys were palpable and the diagnosis of bilateral renal tumor was entertained. The patient soon died of uremia, and at autopsy there was found a bilateral lymphosarcoma of the kidneys with involvement of the periaortic lymph glands and metastatic lesions to the spleen.

The kidneys weighed 4,400 gm. and 68 per cent of the parenchyma of both kidneys was replaced by

a soft grayish tumor mass; this same type of tumor mass was present in the spleen. Microscopically, the renal parenchyma varied from the best preserved portions with arteriolar thickening and hyperemia to complete disappearance and replacement with lymphosarcomatous tissue.

The author briefly summarizes the literature on bilateral renal tumors other than sarcomas and tabulates various types of these tumors reported in the literature. The following gives an idea of the number of bilateral cases reported: carcinoma, 9; hypernephroma, 13; Wilms' tumor, 13; and miscellaneous bilateral renal tumors in 2 instances (cancer on one side with hypernephroma on the other, and sarcoma on one side and hypernephroma on the other). The author thus gathered a total of 77 cases of bilateral renal tumors from the literature.

ROBERT LICH, JR., M.D.

Villa, J. M. J.: A Study of Tuberculous Strictures of the Ureter and Their Complications (Estudio de las estrecheces tuberculosas del ureter y sus complicaciones). *Arch. espan. urol.*, 1946, 2: 301.

The majority of authors agree that tuberculosis of the excretory ducts of the kidney is secondary to renal tuberculosis.

Tuberculous lesions of the kidney may be superficial and limited to the mucosa, or deep, invading the entire thickness of the wall. Superficial lesions appear in the form of granulations or ulcerations while the deep lesions are usually confluent or caseous necrosis or regression with partial cicatrization of the ureter may occur. Elimination of caseous necrotic sheath takes place gradually and is accompanied by an increasing perireteral sclerosis. If regressive processes predominate, tuberculous formations may disappear completely and newly formed embryonal tissue completely and the cicatrization and organization.

A stenosis of the affected portion of the ureter leads to dilatation of the proximal fragment. Such stenosis may be caused by a massive infiltration of the ureteral wall, caseous formations, or fibrous cicatricial tissue. Adhesions between the involved portion of the ureter and adjoining organs, such as the psoas muscle, spermatic vessels, seminal vesicles, and iliac blood vessels, may develop. As a result of complete obstruction of the ureter a pyonephrosis or an enormous enlargement of the kidney may result.

An infection may spread from the kidney to the ureter either by contiguity or through the urine, blood, or lymph.

Clinically, tuberculosis of the ureter causes urinary symptoms and lumbar pains. Increased frequency of micturition, nocturia, hematuria detectable macroscopically or microscopically, a smarting sensation at the end of urination, and pyuria are frequent symptoms. The lumbar pains may appear in the form of the characteristic kidney colic or in the form of localized pains not influenced by movements of the body.

Cystoscopic examination is very valuable for the diagnosis. Asymmetry of the trigonum, caused by a shortening of the tuberculous ureter, and also Fullerton's sign justify the suspicion of a tuberculous ureter. Urography is also an important diagnostic aid.

The treatment of tuberculous strictures of the ureter is the same as that for renal tuberculosis, namely nephrectomy. No faith should be placed in spontaneous cure.

JOSEPH K. NARAT, M.D.

BLADDER, URETHRA, AND PENIS

Pulvert Gorro, A.: Diverticulum of the Bladder. A Contribution to the Diagnosis and Treatment (Diverticulos vesicales. Aportación a su diagnóstico y tratamiento). *Arch. espan. urol.*, 1946, 2: 263.

In examining the bladder diverticulum it is well to use a cystoscope at an angle of 135 degrees, so that the tip of the instrument can be seen in the field of vision. In addition there should always be an extrography with iodized oil (Abelló), the occasion being utilized, especially in older patients, to interrupt the ductus deferens operatively in anticipation of a possible postoperative epididymitis later.

For the operation of extirpation of a possible diverticulum the author employs the extraperitoneal, extravesicular approach to the bladder; this is quite easy through a midline suprapubic incision for diverticula of the anterior bladder wall, or through a lateral abdominal incision for the laterally located diverticula. However, when the sac originates from the posterior wall the peritoneal covering must be separated from the bladder; this can be done in many instances by blunt separation of the peritoneal covering through a midline incision with the scissor of the outermost layer of the peritoneal wall where the peritoneal covering is of the size of a dollar or more. In some instances a breach may firmly adhere to the peritoneal sac, the adherent area left attached to the method described by Voeckler (*Urologische Operationstechnik*, 1924: p. 376). The bladder immediately closed again with sutures according to the method described by Voeckler.

of filling is controlled by the urethral sound. The bladder from the operator's hand on the bladder or by pressure taken in the region of the ductus deferens—must be separated from its bed, and the diverticular sac is apt to be displaced—and in the region of the ureter, when the neck of the sac takes origin down close to the base of the bladder, as this structure is apt to be involved in adhesions. Particular care must also be taken not to interfere with the blood supply to the ureter, and when this is impossible a neoinplantation of the ureter into the bladder may be indicated.

The author states that he has seen instances in which the ureteral orifice was involved in the diverticulum but he does not specifically state that he has ever operated upon such a case; however, this would probably also be an indication for neoinplantation. The muscular collar of the neck of the diverticular sac is cut through down to the mucosa and peeled back and the neck is doubly ligated and cut between the two ligatures. The stump is then buried, first with a circular suture (pursestring) in the muscular neck and then the whole is invaginated by interrupted sutures. Finally, a rubber drainage tube and a couple of strips of gauze are led up to the suprapubic incision, or if the sac has been too deeply embedded a drain is led out through the perineum, according to the method of Geza Illyes of Budapest or a modification thereof. The use of an indwelling catheter for a period of 4 or 5 days completes the technique.

The author does not favor marsupialization of the diverticular sac with cauterization of the lining mucosa because of the long drawn out process of healing and the chance of secondary hemorrhage from the marsupialized surfaces.

JOHN W. BRENNAN, M.D.

Marshall, V. F., Pollack, R. S., and Miller, C.: Observations on Urinary Dysfunction after Excision of the Rectum. *J. Urol.*, Balt., 1946, 55: 409.

Urinary dysfunction is much more common after excision of the rectum than after surgery performed above the pelvis (exclusive of neurosurgery).

The charts of 600 consecutive patients having operations upon the large bowel were reviewed. One hundred and eighteen, or 19.66 per cent, had severe urinary difficulty. Surgical procedures for the condition, however, were done on only 17, or 2.83 per cent.

Since the perineal surgery seems to be the main cause of the urinary complications, the author attempted to determine the conditions which might result from the perineal procedures that at least theoretically could produce such complications—complete urinary retention, paradoxical incontinence, residual urine, difficulty in voiding, and sometimes true incontinence. Urinary infection was the rule but it was almost always secondary.

First, trauma alone could cause urinary obstruction. Edema from trauma alone, however, would usually pass in a few days. Hematomas should be discovered, and furthermore should eventually be out of consideration because they either organize and shrink, or liquefy. Ligation of the urethra would hardly go unnoticed. Stricture of the urethra would certainly be found on examination and the indwelling postoperative catheter should prevent it to a large degree. Acute angulation of the urethra would also probably be prevented by the indwelling catheter. Cystourethrograms on 13 patients having urinary difficulty after perineal rectal excision did not show acute angulation or stricture. Formation of a

mechanical block by inverted tissue into the bladder neck or urethra seems theoretically possible, but the cystourethrograms, and the endoscopic examination of more than 20 patients after rectal excision, lend no support to this possibility as a common cause. Hence trauma per se and obvious direct mechanical obstruction seem to play insignificant roles in the vast majority of patients having more than quite temporary difficulty.

Second, interference with nerve control must be considered. Before transurethral resection was used on these patients, most of these complications were ascribed to a neurogenic bladder. Tradition, then, favors this idea. Simple transurethral prostatectomy has relieved too many who, after resection, have no indication of neurogenic dysfunction. Of course, transurethral resection can greatly improve the function of some neurogenic bladders, but it does so by mechanical, not neurological means, the neurological status remaining. Furthermore, good results are not as easily or frequently obtained with neurogenic bladders as in uncomplicated prostatism.

Bladder dysfunction is more common after perineal excision of the rectum than after other operations on the large bowel.

The authors have been unable thus far to demonstrate neurogenic dysfunction as the underlying cause.

Surgical removal of obstructing tissue at the bladder neck will rectify most of these complications, but not all.

Certain clinical observations led to a theory of the mechanism whereby these complications usually occur.

Application of this theory to the small group of patients continuing to have dysfunction after all obstructing tissue had been removed has given encouraging results. The theory is concerned mainly with elevation and fixation of the bladder and urethra. In practice this was performed suprapubically.

The group of cases here reported is small and too positive deductions must be avoided, but these observations may help to clear up some of the obscure factors concerning the mechanism of urinary control.

JOHN A. LOEF, M.D.

GENITAL ORGANS

Alcala Santaella, R.: The Clinical Anatomy of Prostatic Tumors (Anatomia clinica de la tumoracion prostática). *Arch. espan. urol.*, 1946, 2: 230.

In a previous publication, the author has reported his dissections on the musculature of the urinary bladder and his x-ray studies of the normal act of micturition, and in this article he turns his attention to the abnormal conditions produced by the enlargements of the prostate gland. Dissection was made of a number of postmortem specimens obtained from patients who had died before the second stage of the prostatectomy could be accomplished. This of the prostatectomy was combined with molds of the bladder cavity in

wax, showing the effect of the growth of the adenoma of the prostate on the size and shape of the bladder cavity.

Even during the operation on these patients it is noticeable that the morphological variations present do not explain the clinical symptoms. The most important phenomena manifested by prostatic enlargement, chronic retention, or frequency of urination, frequency of urination, and acute retention. The on the basis of his studies, as a compensatory process on the part of the detrusor mechanism to overcome the condition of hypertonia of the sphincter muscle, which is in turn induced by congestive phenomena and irritation of the nervous mechanism supplying the neck of the bladder caused by the encroachment of the enlarging prostate on this region.

However, in the author's opinion, the symptoms of dysuria have a different explanation: They are essentially a phenomenon of muscular alteration. As the prostatic adenoma enlarges, its growth is directed upward toward the floor of the bladder by the resistance below of the external sphincter and membranous urethra which remain intact (incontinence rarely develops following suprapubic prostatectomy). However, the internal sphincter is dilated and displaced downward and the neck of the bladder of the bladder. Now, normally, the so-called neck of the bladder continues beyond the muscular triangle of the trigone but drops downward at an angle of 95 degrees; this the author designates as the posterior lip of the neck of the bladder, and he has demonstrated roentgenologically that it retracts under the pull of the muscles of the trigone and, to some extent, of the rest of the muscles of the bladder and the neck of the bladder and permits the detrusor mechanism to expel the urine in the act of micturition. In the presence of prostatic tumor the growth dilates the internal sphincter and pushes against the anterior edge of the trigone (posterior lip of the neck of the bladder); this modifies the angle of the structure and interferes with its mobility. Since the retractability of the posterior lip seems to be essential for the free act of micturition, rigidity or lack of free mobility is assumed to cause a hindrance. As a matter of fact, chronic retention is seen in conditions of stricture or connective tissue infiltration of the bladder neck; and tonometric studies on the bladder show that also in cases of prostatic patients a rise in pressure inside the bladder from a normal reading of 30 c.c. of water to 75 c.c. occurs before micturition is effected. That is, the mechanism of micturition is a complicated phenomenon, requiring an equilibrium between the musculature of the bladder neck, the internal sphincter, and the detrusor muscles, and it is the disturbance of this equilibrium by the obstacle in the form of the prostatic tumor which is responsible for the chronic retention in the afflicted patient. It is only one step further to the stretching and dislocation of this musculature to the point of

paralysis or impotence which leads to the condition of acute retention with all its consequences.

JOHN W. BRENNAN, M.D.

Lowry, E. C., Beard, D. E., Hewitt, L. W., and Barber J. L.: Tumors of the Testicle. *J. Urol.*, Balt., 1946 55: 373.

Tumors of the testicle comprise approximately 4 per cent of all malignancies of the genitourinary system in civilian hospitals. Teratoma of the testicle represents approximately 70 per cent of all neoplasms of the genitourinary system, and 7.86 per cent of all malignant tumors.

For many years there has been quite a diversification of opinion regarding the classification of teratoma of the testicle. The classification employed by the majority of urologists is that suggested by Ewing, which is based upon the microscopic appearance or cell type of the tumor. Malignant tumors of the testicle are considered to arise from a cell which is capable of producing tissue resembling that arising from any or all germinal layers. It would appear that these tumors have a common origin since in this and other series of cases, all types of tissue, embryonal carcinoma, seminoma, adenocarcinoma, and adult elements, have been found in a single tumor, and various combinations of the above have frequently been observed.

The chief complaint in 86 per cent of the cases reported herein was "painless swelling of the testicle," which in most cases was accompanied by other symptoms referable thereto, such as heaviness in the scrotum, and the mechanical interference of the enlarged testis during exercise. Six patients in this series complained of pain in the affected testicle, the pain varying from a dull ache to sharp incapacitating pain. These cases were all of the type with a history of sudden enlargement of the testicle within a few days prior to the onset of pain.

Four patients in this series were admitted with complaints referable to the spread of the disease: 2 with masses in the left supraclavicular fossa, and 2 with hydronephrosis. These patients were not aware upon admission that they had an enlarged testicle.

Other symptoms such as weight loss, cough, loss of appetite, indigestion, and backache were frequent, particularly in cases with demonstrable metastasis.

The diagnosis of teratoma of the testicle can, with few exceptions, be made with accuracy by physical examination.

The enlarged testicle invariably maintains the configuration of the normal testis, no matter what size it attains. The tumor is usually of uniform consistency and is firm and rubbery. The affected organ is usually stony hard in the adult type of tumor.

The successful management of teratoma of the testis depends mainly upon an early diagnosis. The average interval in these cases between the first symptoms noticed by the patient and operation was 10 months. Allowing sufficient time for the Friedman modification of the Aschheim-Zondek test to be of diagnostic value is a cause of delay in many cases.

Malignancy of the testicle may be confused with epididymitis, orchitis, hydrocele, hematocele, torsion of the cord, tuberculosis, and syphilis of the testicle. The quantitative analysis of the urine for prolan A has proved to be a valuable adjunct in the diagnosis of these tumors in some clinics. Not only is the diagnosis made, but the type of tumor is said to be predicted with a fair degree of accuracy. In the authors' hands this test has not been found of such value, either as a diagnostic aid or in predicting the prognosis of the case, chiefly because of the technical difficulty in performing the test.

An excretory urogram is of value in locating abdominal metastasis not detectable by other means. The retroperitoneal lymph nodes to which these tumors spread lie along the course of the ureters and enlargement is detected by the observation of filling defects in the ureter, displacement of the ureter or kidney, or hydronephrosis in more advanced cases.

Metastases from teratoma of the testis are prone to occur early and with rare exceptions are spread by way of the lymphatics. The lymphatic drainage of the testis is almost entirely to the periaortic nodes. The main lymphatic channels accompany the spermatic vessels from the testicle through the cord as far as the level where the vessels cross the ureter, and from here they lead directly to the periaortic nodes from the level of the bifurcation of the aorta to the celiac axis at a region near the renal pedicles.

Metastases having once entered the regional drainage nodes, rapidly spread from the celiac axis to the subdiaphragmatic nodes, thence to the mediastinum, and by way of the thoracic duct appear at Virchow's node in the supraclavicular region. Once this node is involved one can be relatively sure that extension has occurred to the mediastinum and upper abdominal lymph nodes.

In this series of cases, metastases were found to exist in 32 cases, spread invariably by way of the lymphatics. In 1 case in which the patient died after the vena cava was invaded by direct extension of the metastases along its course, death resulted from a pulmonary embolus.

This group of 100 cases was treated in general by the same method, that is, after the method described by Dodson. In this method the testicle is removed after ligation of the spermatic cord at the level of the internal inguinal ring. An incision is made parallel to the inguinal canal on the affected side, from 6 to 10 cm. in length, according to the size of the affected testicle. The incision is not extended into the scrotum. The external oblique is divided in the line of its fibers for an equal distance. The spermatic cord thus exposed is ligated at the level of the internal inguinal ring before the testicle is disturbed. The testicle is then delivered into the wound and removed by gentle traction. In this series of cases a more radical orchectomy with dissection of the lymph glands on the affected side was not performed. Since many cases have metastases on the opposite side, lymphatic dissection on the affected side is not considered a curative procedure. A radical retroperitoneal ab-

dominal lymphatic dissection was performed elsewhere in 1 of the cases reported herein. Large abdominal metastases developed later on the opposite side and the patient is now bedridden from the disease.

X-ray therapy was generally started as soon as the patient could comfortably be transported to the x-ray department—in from 3 to 5 days after operation.

All treatments were given with the following factors: 220 k.v. (G. E. Maximar), 15 ma., 50 cm. target skin distance, from 0.5 to 1 mm. of copper and 1 mm of aluminum filter added (half value layer from 0.9 to 1.35 of copper), and from 42 r. to 31 r. per minute measured in air.

The plan of x-ray therapy depends upon the presence of metastases before treatment, the duration of symptoms for 6 months or longer, or the absence of metastases at any time and the duration of symptoms for 6 months or less.

The results obtained to date in the treatment in this series of cases have been somewhat discouraging. Twenty-four patients had definite demonstrable metastases upon admission and in 2 others metastases developed while they were in the hospital. Subsequent examination revealed that 12 additional patients now have demonstrable metastases. When x-ray therapy was administered to the cases with metastases, there was an appreciable diminution in size or disappearance of the metastatic mass in only a few. In the cases which responded initially there was subsequent recurrence. In several cases definite advancement of the disease was noted during the course of the treatment.

Fourteen patients in the group are now dead; an additional 8 are bedridden and are dying from the disease. Of the 100 patients, 68 are now living and well and are without evidence of metastasis at this time. The length of time that has elapsed since operation in these cases varies from a few weeks to three years.

MISCELLANEOUS

Weens, H. S., Newman, J. H., and Florence, T. J.: Trauma of the Lower Urinary Tract. *N. England J. M.*, 1946, 234: 357.

The authors present a series of 7 cases featuring trauma of the lower urinary tract in which the diagnosis was made satisfactorily by the retrograde injection of a radiopaque contrast medium. Disadvantages of other diagnostic procedures are cited. The clinical history and physical examination may be inadequate for accurate determination of the site and extent of the injury. Urinalysis may be misleading. Urethral catheterization, in addition to introducing further trauma, may not rule out the possibility of vesical rupture since urine may be drained from the peritoneal cavity. Cystoscopy, in addition to being traumatic, may fail to establish a diagnosis. Pneumocystograms present a problem in maneuvering the injured patient between the recumbent and upright positions and, further, introduce the hazard of air embolism.

Fig. 1. Left, this is a retrograde cystogram showing extensive intraperitoneal extravasation. Right, note the accumulation of contrast medium in dependent portions

of the peritoneal cavity (a) and the paracolic recesses (b), as well as the scalloped filling defects of the contrast medium produced by the intestinal loops (c).

Retrograde urethrograms and cystograms present a diagnostic method by which any injury which interrupts the continuity of the urethra or bladder may be demonstrated with a minimum of manipulation, pain, and trauma. In cases of vesical rupture, the cystogram assumes a highly characteristic pattern. In intraperitoneal rupture, the opaque medium

has a tendency to accumulate and penetrate into the more dependent portions of the pelvic peritoneal cavity when the patient is in the supine position. The distended intestinal loops cast round or cylindrical filling defects in the extravasated contrast

Fig. 2. Another retrograde cystogram showing intraperitoneal extravasation; characteristic filling defects in extravasated medium produced by intestinal loops.

Fig. 3. This is a retrograde urethrocytogram. Note the extensive extravasation in the region of the posterior urethra.

medium, which are easily recognized. In addition, the accumulation of contrast medium as a bandlike or linear density along the peritoneal reflection of the flanks (the paracolic recesses) produces a highly significant roentgenologic sign. The haustral markings of the colon and loops of small intestine may produce a scalloped impression along the inner aspect of these bands of increased density.

Posterior urethral and extraperitoneal vesical ruptures are characterized by more or less diffuse penetration of the contrast medium into the tissues of the pelvic floor and prevesical space. In massive extravasations the medium may assume a sunburst-like appearance. Smaller extravasations are represented by streaky and feathery bands extending from the urinary bladder toward the surrounding soft tissue structures. The urinary bladder may assume an elongated pear shaped appearance or may be dislocated in any direction.

A combination of intraperitoneal and extraperitoneal rupture of the bladder, not encountered in this series, might be expected to assume the characteristic roentgenologic features of both conditions.

Intravenous pyelograms may fail to reveal vesical rupture, even though an apparently satisfactory cystogram is produced, either because of insufficient concentration of the contrast medium or insufficient pressure to produce leakage from the bladder. Cystography by means of a urethral catheter introduced into the bladder may not indicate the presence of urethral rupture, since the catheter is carried past the site of injury. In this case, retrograde urethrography is a necessary adjunct.

The authors conclude that retrograde urethrography is a simple, safe, and accurate method for the detection of trauma of the lower urinary tract.

CLARENCE V. HODGES, M.D.

Exley, M.: Penicillin Treatment of Urinary Infections Caused by Pyogenic Cocci. *J. Urol., Balt., 1946, 55: 435.*

One hundred and one cases of urinary tract infection with pyogenic cocci were treated with penicillin.

Penicillin is less satisfactory in the treatment of urinary tract infections than in other types of infection because the majority of the former are caused by organisms which are relatively insensitive to penicillin, i.e., the bacillus coli and the bacillus proteus. However, penicillin is of definite value in the treatment of pyogenic cocci in the urinary tract. It is not subject to action interference by pus, tissue autolysates, or peptones as are the sulfonamides. Of the sensitive organisms found in the urinary tract, beta hemolytic streptococci and most staphylococci can be destroyed. The streptococcus viridans and fecalis were found to be only moderately sensitive. The successful treatment of staphylococcal infections requires twice the dosage necessary for streptococcal infections. Gram negative rods, including the bacillus coli, contain penicillinase which destroys the inhibitory effects of penicillin. Because of the non-susceptibility of these organisms in a mixed infection

the value of associated sulfonamide therapy is suggested. Although the bacillus proteus does not produce penicillinase, the action of penicillin on this bacillus and on bacillus pyocyaneus is nil.

With few exceptions, organisms unable to inactivate penicillin were susceptible to its action if free urinary drainage was present and anatomical abnormalities were previously eliminated. Infections complicated by the presence of stone, hyperplasia of the prostate, bladder diverticula, and urethral stricture require more than the administration of penicillin to effect a lasting cure. In 4 cases of calculous pyelonephritis failure occurred. After removal of the offending calculi followed by penicillin treatment the patients became asymptomatic and sterile urine cultures were obtained.

Because of the fact that penicillin is bacteriostatic and not bactericidal the treatment period should be no less than 3 days. The best results were obtained in the 6 day group and with a daily dosage of from 250,000 to 350,000 Oxford units. Cure was obtained in 78.2 per cent of the susceptible pyogenic cocci infections in this series.

An insufficient amount of penicillin may result in the development of resistant strains of the organism. Therefore, care should be taken to prescribe a sufficiently large dose initially.

FREDERICK R. LIESERTRAL, M.D.

Sarnoff, S. J., Freedman, M. A., and Hyman, A. A.: The Treatment of Bacillus Proteus Infections with Nu-455. *J. Urol., Balt., 1946, 53: 417.*

In a recent study on Nu-455, it was found that this sulfonamide derivative had several features to recommend its clinical trial. It is of low toxicity, has a rapid absorption rate, holds a blood level well, and gives high concentrations in the urine. It is many more times soluble than the next most soluble sulfonamide, and even in the absence of concomitant alkali medication, fails to give laboratory evidence of renal irritation or precipitation in the kidneys. The latter fact is of considerable importance in the treatment of bacillus proteus infections of the urinary tract, since this organism itself renders the bladder urine alkaline, which makes it difficult to determine whether alkali medication has succeeded in raising the pH of the urine. Since crystalluria was not encountered at the varying hydrogen ion concentrations of human urine without alkali medication, it was believed that pharmacologically this drug was particularly well suited to the treatment of bacillus proteus infections.

Nu-455 may be administered orally, intravenously as a 10 per cent solution of its lithium salt, or intramuscularly in the same concentration. It may also be used for local irrigation.

The treatment of a series of 15 cases of bacillus proteus infections with Nu-455 was undertaken. All but 1 were infections of the urinary tract. With 1 exception, 3 positive cultures were required before any patient was included in the study. At least 3 successive negative cultures were required before

bacteriologic reversal was assumed. All specimens were placed in media to which para-aminobenzoic acid had been added. The dosage schedule varied between 5 and 8 gm. per 24 hours.

Nine of 11 cases returned 3 successive negative cultures, the remaining 2 were modified by therapy, but did not meet the criterion for bacteriologic reversal (3 successive negative cultures). The 4 other cases were apparently entirely uninfluenced by drug therapy. In the patients with 3 successive negative cultures, the first negative culture was obtained from the third to the thirteenth day, the average being on the sixth day.

Of the 4 patients completely unaffected by Nu-455 medication, 1 had a squamous cell carcinoma of the bladder, and cystoscopy revealed, on several different occasions, that the tumor was necrotic and contained areas of devitalized tissue. The second patient received his course of therapy between the first and second stages of a suprapubic prostatectomy, at a time when a large, obstructing prostate and a suprapubic tube were still in place. The third case was treated inadequately, with only 22 gm., during the first course of therapy. The drug was stopped at this time because of a febrile response, which was at first attributed to the drug. The patient's subsequent course indicated that this assumption was not true. A transurethral resection was followed by the development of a retroperitoneal abscess from which the bacillus proteus was cultured. Further therapy in the presence of this condition failed to eliminate the organism. The resistance of this organism may possibly be attributable to previous exposure of this

strain to inadequate amounts of the drug. The fourth case also received the course of therapy between the first and second stages of a prostatectomy, with prostatic obstruction and a suprapubic tube present. Sulfadiazine did not affect this patient's organism.

Of the 6 patients from whom 3 successive negative cultures were not obtained, 4 had suprapubic tubes *in situ*, and 1 had a continuous indwelling catheter. The sixth case was a clinical cure in the sense that the urine became crystal clear and the patient was symptom free after therapy. The 6 bacteriologic failures might have been anticipated, since a suprapubic wound infected with the bacillus proteus is relatively resistant to the usual blood concentrations of the drug and will serve as a nidus and continually seed the urine with organisms. The inhibitory effect of pus on the action of sulfonamides and the difficulty of eradicating infection in the presence of tumor, stasis, or stone are well known. Nevertheless, it will be noted that in 3 of the 9 patients in whom a bacteriologic reversal was produced, there were open wounds at that time.

In several patients the bacillus pyocyaneus was also present in the urine, but in only 2 patients did the time relationship suggest the possibility that the bacillus pyocyaneus might be responsible for the elimination of the bacillus proteus.

Other organisms, such as the enterococcus, bacillus coli, and bacillus pyocyaneus, found concomitantly with the bacillus proteus, did not seem to be affected favorably by therapy with Nu-455.

JOHN A. LOEF, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Grace, E. J., and Bryson, V.: Penicillin for Osteomyelitis. *J. Am. M. Ass.*, 1946, 130: 841.

With regard to the treatment of patients with chronic osteomyelitis, the authors state that the medical profession is divided into a majority group who favor radical surgery with extensive saucerization followed by skin grafting if necessary, and a minority group who place primary reliance upon chemotherapy in the treatment of chronic osteomyelitis, with surgery reduced to a minimum compatible with successful treatment.

The authors' studies of penicillin-detergent combinations are designated to eliminate by means of the detergent the isolation of penicillin-susceptible bacteria in sequestra, sclerosed bone, abscesses, poorly vascularized sinus tracts, and soft tissue scars. The bacteria are then eliminated by the penicillin which has increased antibacterial properties as a result of the detergent.

The therapeutic program consists of a complete physical examination with the correction of obvious deficiencies such as anemia and focal infection. The authors stress the importance of the primary elimination of evident foci of infection. After the preliminary steps, the patient is hospitalized and every 3 hours receives injections into each sinus tract of 3 c.c. of penicillin consisting of 200,000 units dissolved in 25 c.c. of the wetting agent, aerosol O.T. or sodium tetracycl sulfate 0.1 per cent. This is supplemented by intramuscular injections of 20,000 units of penicillin every 3 hours for four doses and then 20,000 units every 3 hours night and day. For the topical application, 20,000 units per cubic centimeter are sometimes used. Only 25 or 50 c.c. are prepared at one time in order to insure a fresh solution. At times, dressings wet with tyrothricin and covered with a compression bandage are used.

Seven cases are reported with 1 definite failure.

DANIEL H. LEVINthal, M.D.

Purriel, P., Cagnoli, H., and Espasandín, J.: Brucellosis Spondylitis (La espondilitis brucelosa). *Rev. ortop. traumat.*, B. Air., 1945, 15: 3.

Practically 100 per cent of the cases of brucellosis in Uruguay so far have been of the abortus variety. In the acute phase of the disease, the general signs and symptoms dominate the picture, and in only 1 of 150 acute cases, destructive changes of the spine were found by the authors. On the other hand, localized changes are very frequent in the chronic phase, i.e., in ambulatory patients. This difference in frequency of general and localized changes is typical for brucella abortus infection, and does not hold true for infections produced by the brucella suis or melitensis.

The lesions of the spinal column are either destruction of the bone (spondylitis) or they involve the bones and joints (spondylarthrosis). They may occur in any age group, and in either sex, yet men outnumber women at the rate of 8 to 1, and in the authors' series all of the patients were males. Most frequently the lumbar spine is involved, yet thoracic involvement is not rare, and cervical spondylitis due to brucellosis occurs occasionally.

The authors are amazed that up to 1939 only 66 cases of disease of the spinal column due to brucellosis had been described in the United States, as they found 62 per cent of their cases of spinal column disease due to this condition. They explain this discrepancy as follows: (1) there have not been any systematic roentgenological studies of the spinal column in brucellosis; (2) the lesions very often produce only very slight symptoms or none at all, (3) in the acute stage, when the patient complains of backache, roentgen-ray studies are usually negative.

The authors roentgenographed their brucellosis cases systematically every 3 months, studying the spine. This procedure not only revealed numerous lesions, but permitted the study of their evolution.

There are three clinical types of brucellosis of the spine:

1. The acute condition in which the patient suffers from backache. While this is the period of septicemia and of the onset of inflammatory processes in the bone marrow, x-ray studies of the spine are negative at this time.

2. The chronic condition in which the pain is localized, intense, unrelieved by rest, and intensified by movements; it may be bilateral and/or descend (sciaticlike). There are contractures and other muscular impairments. There are roentgenographic changes. The agglutination reactions in this stage have diminished or disappeared, and the blood culture is negative. The only diagnostic findings are a positive skin test and opsonic index. In addition, the patient's history and epidemiologic facts contribute to the diagnosis.

3. Old vertebral lesions. The diagnosis in these cases is especially difficult, as there is a discrepancy between the number of patients infected (contacts) and those actually afflicted. Positive skin reactions and opsonic indices are not enough to ascribe a given lesion with certainty to a brucellosis infection, a fact which is of considerable scientific as well as legal importance.

WILLIAM E. RICKETTS M.D.

Stout, A. P.: Rhabdomyosarcoma of the Skeletal Muscles. *Ann. Surg.*, 1946, 123: 447.

In a careful survey of the literature on rhabdomyosarcoma of the skeletal muscles, the author has been unable to find satisfactory information concern-

ing the biologic habit of the tumor and especially about the efficacy of treatment. To the already published cases he has added 14 of his own, making a total of 121 cases that are analyzed in this article.

The rhabdomyoblastic tumor cell is extremely variable in size but, in general, it is rather large and assumes one of three different shapes. It is rounded, strap shaped with two or more nuclei arranged in tandem, or racquet shaped with a single nucleus at one expanded, rounded end and a tapering body extending outward from this for a variable distance. With suitable stains either cross striations or longitudinal myofibrils, or some vague suggestion of their formation should be distinguishable in the majority of cases. It is usually not easy to find this differentiation even with good preparations and one must be willing to make a painstaking search with high magnification. The cytoplasm of all these cells is more or less strongly acidophilic. In 9 of the 14 new cases recorded one or the other of these differentiating features was found.

These tumors develop in animals as well as in man and they have been found in certain definite systems and regions of the body. These are more particularly the genitourinary system, the heart, upper respiratory and alimentary tracts, and the orbit; sporadic examples have been found in the lung, breast, esophagus, suprarenal glands, and brain. The writer was able to locate reports of 107 cases which had developed in the striated muscles and other soft parts of the body.

Because of other varieties of muscle cell tumors a simplified nomenclature for this group is suggested with the following terms: smooth muscle cell tumors—leiomyoma, leiomyosarcoma; striated muscle cell tumors—granular cell myoblastoma (benign and malignant types); rhabdomyoma of the heart muscle; rhabdomyosarcoma; and undifferentiated myosarcoma.

There were 62 males and 52 females among the 114 patients of whom the sex was recorded. The age variation was extreme and cases were reported in all decades including the ninth with the preponderance in the fifth and sixth decades. In almost every case the tumor developed either within or attached to a peripheral striated muscle. The distribution of the 123 tumors (2 patients each had 2 independent tumors) was as follows: lower extremity—52 cases; upper extremity—17 cases; trunk—31 cases; head and neck—19 cases; diaphragm—3 cases; and psoas muscle—7 cases. The duration of the disease is variable and in 1 case the clinical course from the onset of symptoms until death was only 2 months, while in another the tumor persisted after 50 years. One must be very cautious in predicting the probable duration of these tumors. Commonly the only symptom is tumor, which in 88.5 per cent developed without any history of antecedent trauma and, often, without pain or interference with function. Sometimes the growth compromises the overlying skin and the tumor fungates, which may also happen after biopsy. The size and consistency are variable. These tumors

infiltrate insidiously, and metastases through the blood and lymphatic channels are not uncommon, with the lungs as the most favored repository.

Only 4 symptom free 5 year survivals are reported among the 121 cases, 108 of which received treatment. One of these was treated by amputation alone, 1 by excision alone, and the other 2 by excision and radiotherapy.

From the published data it is impossible to select the best form of treatment arbitrarily. It is manifest, however, that in a very large number of cases the first procedure was an inadequate excision, and that one should be able to cure this neoplasm more often if it is attacked earlier and in a more radical manner. An extended study of cases of malignant tumors of the peripheral soft parts and bones has convinced the author that they should not be attacked by blind removal before definite knowledge of their nature is obtained by biopsy. If the tumor is treated without knowledge of its nature one runs the hazard of removing too much or too little, usually the latter. A small biopsy with the minimum amount of trauma will furnish the information necessary for proper action and of itself will do no harm. In the case of the rhabdomyosarcoma, treatment should certainly be radical with the removal of a large block of surrounding uninvolved tissues. This may or may not mean amputation.

The author's 14 cases are described in abstract form and some are illustrated with photographs of the patients, specimens, and microscopic material. The detailed clinical data of the 121 cases are presented in tabular form and an excellent bibliography is added.

CHARLES A. WALTMAN, M.D.

FRACTURES AND DISLOCATIONS

Soeur, R.: Intramedullary Pinning of Diaphyseal Fractures. *J. Bone Surg.*, 1946, 28: 309.

In 1940 Kuentscher first demonstrated convincingly that osteosynthesis could be secured along the medullary cavity of the long bone. He described longitudinal fixation by means of metallic material occupying the full length of the medullary space. The material was a rod of as large size as the bone canal permitted. The material was introduced by an extra-articular route as far from the fracture site as possible, and without exposure of the fracture. The material was completely buried. The end of the prosthesis, which extended beyond the bone, was covered by the soft parts and the skin. The reduction had been retained by external maneuvers before the intramedullary fixation. After consolidation of the bone, the prosthesis was extracted. The author's experience with this method was secured with a total of 55 operations.

The chief objection to medullary pinning is the destruction of the bone marrow. Even if the prosthesis should destroy all of the medullary content, Soeur believes that the individual is able to do without the hematopoietic element in one of the long bones. In so far as the blood of the patient subjected

Fig. 1. Prostheses and pin driver. A. Straight pin of grooved bar of steel (V-2A). One end is pointed, the other shows a small eye. In profile these pins are in the form of a U. For a femoral diaphysis, the diameter of the pin is usually 8 mm. The thickness of the sides of the U is 2 mm. For the humerus and the ulna the pins are similar, but shorter and thinner. B. Tibial pin, made of the same material as the straight pin, and from 6 to 8 mm. in diameter.

It is curved at both ends. The point of the curve is generally 1.5 cm. from the end. C. Radial pin, 5 mm. in diameter. It has a single curve. D. Threaded rod for the ulna and radius, from 2 to 3 mm. in diameter. E. Graduated pin driver. The guiding tube has been slid over the pin up to the bone. The graduations on the mandril show the extent to which the pin penetrates the bone.

to medullary pinning is concerned, the changes are very mild and of little concern to the surgeon. The risk of fat embolism is of more importance. Statistics based on more than 100 fixations, which have been published, affirm that the method does not predispose to the danger of embolism. Only once has the author seen a postoperative pulmonary embolism. At present the risk appears to be slight. In his opinion, the septic complications—all other factors being equal—are less to be feared after medullary pinning than following other methods of osteosynthesis. There is little trauma and the method entails less disturbance of the muscles and manipulation of the fragments than occurs with open procedures. The method is contraindicated in compound frac-

tures. According to the author the presence of a foreign body in the medullary cavity does not in itself predispose to infection. Osteomyelitis in the entire diaphysis need not be feared, even when the operative site becomes infected.

The operation causes little shock. Medullary osteosynthesis is a safe procedure. The incision is short; there is little hemorrhage; bleeding is reduced to a minimum since the site of the fracture is not often opened. The postoperative well-being and objective state of the patient is truly astounding and they remain so in the days that follow.

2. The prosthesis is simple. The bloodless reduction of the fracture is tedious because of roentgenographic control and successive corrections. The op-

Fig. 2. Extractor. A. The instrument is 18 cm. long. A hook fits into the eyelet of the pin. By blows with the tip of the hammer, one frees the prosthesis. This instrument is useful in the operation when it is necessary to retract the pin in order to change its direction. B. Hammer-extractor permits the freeing of a pin when the head of the pin alone

is accessible (after consolidation). The rod, 35 cm. long, has a hook attached to one end and a handle to the other. A metallic mass, weighing 1 kgm., moves freely on the rod. While the assistant holds the handle, the surgeon drives the mass violently against the handle.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS.

281

eration is performed under spinal or local anesthesia. When end-to-end opposition has been obtained the place the operation is easy. With the pin in necessary to perform an open reduction operation, reduction of the fracture is all that is required. It is essential to maintain apposition of the fragments during the time the bed is being prepared for the fitting and while fixation is done.

3. The formation of callous is rapid. The callous forms more quickly if medullary metallic fixation is used than with any other method. It may be that the presence of a foreign body in the medullary canal is responsible for this. The hypertrophy of the callous is more pronounced whenever a thick prosthesis is used and less intense whenever the material is very thin.

4. Early mobilization is possible, because there is no pain, because callous forms rapidly, and because the part of the limb is firmly fixed. Active mobilization begins from the first days following the operation. Patients with operations upon the thigh usually walk about with two canes by the sixth week. Those with operations upon the leg get about by the twelfth day. Patients with operations upon the upper arm are able to contract the deltoid muscle; with operations upon the forearms they can move the fingers. Massage and other forms of physical therapy are generally superfluous, since the joints maintain suppleness and the muscle tone, while the circulation remains normal. Hospitalization is greatly reduced in comparison with that required by other methods of treatment, notably continued extension.

The author described the technique which is recommended for the femur, tibia, humerus, forearm, and other fractures. He gives in detail a description of the type of pin, the position of the patient, the reduction, the introduction of the pin, the osteosynthesis, the postoperative care, the removal of the pins, and the results.

The results obtained in 23 diaphyseal fractures of the femur, 10 of the leg, 9 of the humerus, and 13 of the forearm are analyzed critically. The author outlines the operative indications but does not advise intramedullary pinning in compound fractures. However, he recommends it very highly in closed fractures, especially those of the femur and of the forearm.

ENT. C. ROARSING, M.D.

Narishman, N. S.: Recurrent Dislocations of the Shoulder Joint. *Ind. J. Surg.*, 1945, 7: 125.

The author reviews the anatomy, pathological changes, and the various theories of the mechanism of recurrent dislocation of the shoulder. In 99 cases of recurrent dislocation of the shoulder, 16 of which were operated upon, the author found that the capsule was never lax, the labrum glenoidale was detached from the margin of the glenoid in 11 cases, and no abnormality of the humeral head was seen. There was no tear of the supraspinatus or of the glenohumeral ligaments.

The Bankhart operation was done on 12 patients, the Claimont operation on 2, and the Nicola operation on 2. The results of the various procedures described in the literature are tabulated, and their comparative merits noted.

DANIEL H. LEVINthal, M.D.
Med. J. Australia, 1946, 1: 352.

The author presents a review of 124 cases which he treated in military hospitals in a period of 3 years preceding March, 1945.

Because of the elongated shape of the scaphoid bone and the fact that it lies in the proximal as well as the distal row of the carpal bones, this bone is very susceptible to injury. In a fall, the outstretched hand is held firm by the long forearm muscles and the force traveling through the capitate muscles and scaphoid across the edge of the radius "like a stick across one's knee." In older people and in women, Colles' fractures occur instead, because the stick hyperextends and the lower end of the radius takes the impact of the blow. Some fractures of the scaphoid are discovered accidentally. Some patients seek medical aid because of persistent pain and stiffness after the injury and because of arthritis following nonunion.

Examination of 397 scaphoid bones showed that vascular foramina occur only in the narrow palmar and dorsal surfaces of the bone. In 13 per cent, it was found that foramina did not occur proximal to the waist of the scaphoid bone, which means that fractures occurring proximal to the vascular foramina deprive the proximal fragment of its blood supply. This fragment then supposedly undergoes necrosis. Not only does union occur very slowly, but arthritis develops because of the irregular shaped proximal fragment of the scaphoid bone once union has occurred. Because of these observations, early excision of the proximal portion of the scaphoid has been recommended.

The opposing view recommends excision to be done only if there is definite x-ray evidence of nonunion and necrosis, as shown by irregular mottled densities and partial collapse of the bone fragment.

This view was based on the following observations: The hyperemic stage following fractures, during which the bones decalcify, usually is confined to the first 2 or 3 weeks. It is said that cancellous bone and cartilage survive 3 weeks until a new blood supply is established. If a fractured scaphoid is immobilized immediately after the injury, it is considered that a new blood supply can develop in less than 3 weeks, so that by the time the decalcification has ceased and the proximal fragment will remain in denser than the rest of the bones without necrosis.

The treatment of the fractured scaphoid depends upon whether the patient is seen within 2 months of injury or after a longer period following injury. The early treatment consists of immediate, efficient, and

INTERNATIONAL ABSTRACTS OF SURGERY

persistent fixation of the wrist joint until the x-ray signs of fracture have disappeared. The immediate fixation is very important because the initial bone formation is the most potent force to bridge the gap and the life of the avascular proximal fragment depends upon this early bridging.

Five fractures of the tubercle united in the average time of 15 weeks. Fifty-three cases of fracture through the waist of the scaphoid were kept immobilized for from 15 to 50 weeks; all except 3 united. Seven cases of fracture through the proximal pole required immobilization for from 22 to 47 weeks; all united.

The patients who presented themselves for treatment more than 2 months after injury had a variety of roentgenological changes: delayed union, as shown by decalcification of the fracture line and "cyst" formation; nonunion, as evidenced by sclerosis along the fracture line; and arthritic changes, as manifested by a sharpening of the radial styloid or a narrowing of the radioscaphoid bone. Ten patients with delayed union had treatment for a period of 3 to 9 months; union of the fracture occurred in all of them. Seven patients were operated on by grafting in 1, by drilling in 3, and excision of the proximal fragment in 3, nonunion occurred in all. Thirty-two patients showed delayed union after having been treated for more than 9 months. Twenty-three of them were given a leather splint and 9 were treated; all of them showed nonunion at the termination of the treatment. Three were treated by means of a plaster cast only, and 6 were operated upon, 3 by grafting, and 3 by excision of the proximal pole.

From this review, it is evident that the best treatment for these patients is the application of a leather support since operation proved to be unsuccessful in all of the cases in this series.

In conclusion, it is stated that delayed union of the scaphoid with arthritis should be treated by fixation in a plaster cast. Arthritis with nonunion should be treated by change to lighter work and the application of a leather wrist support.

GEORGE J. REISS, M.D.

Speed, K.: Treatment of Fractures of the Hip; Surgical Technique. *Surg. Clin. N. America*, 1945, 26: 230

This article describes the surgical technique of the treatment of fracture of the hip employing either the three flanged Smith-Petersen nail or Moore pins. The standard operation for this condition is described and is a suitable reference for surgeons interested in the procedure.

For guides in driving the pins, two small strips of tin punched with digits in sequence and with small perforations at the extremities are used as markers. One of these strips is sewn over the middle of the inguinal canal over the region of the head of the femur or acetabulum by skin stitches passing through the perforations. The other strip is sewn to the skin at

a point 2 inches below the greater trochanter. The anteroposterior film definitely shows from which digit of the marker on the outer margin of the hip the operator must initiate his penetration of the neck and head of the femur, and aim at the specified distance of the second marker lying just in line with the head as seen in the roentgenogram. No matter what method of determining the direction of driving the fixation is used, the operator should never neglect roentgenological control before final insertion.

Errors of omission worth consideration are: Incomplete preparation of a sterile operating field, with resulting wound infection.

Failure of roentgenological control during the process and at the end of fixation. The lateral view is particularly necessary to be sure that the head of the femur rides in proper position on the neck. If the head of the femur is not properly placed, the following may result:

a. Insufficient penetration into the head of the femur by the fixation agent because it is too short or incompletely inserted.

b. Too deep a penetration extending into the acetabulum. This may lead to separation at the fracture plane.

c. Rotation of the head fragment during insertion of fixation after insecure reduction or with an improper angle of insertion. This will lead to loss of contact of the fracture surfaces.

Improper postoperative fixation. Care must be taken to avoid stress on the fixation, as this may lead to disjunction.

Errors of commission consist of:

1. Incomplete reduction of the fracture. One should keep in mind the advantage of a slight external valgus.

2. Improper angle of insertion of the fixation agent because of ignorance or disregard of anatomy.

3. Lack of immediate checking by roentgenological control. The operator may be too hurried or overconfident. The check-up should not be put off for several days.

4. Lack of aseptic technique and unskilled operator by too much dependence on mechanical pointers or indicators.

5. Insufficient support of the leg after operation by whatever means the patient requires.

6. Too early unguarded motion, especially abduction of the leg. The nurse must be familiar with the angle of the neck and the necessity for careful handling of a fine adjustment.

7. Too early weight bearing, putting too much faith in the fixation agent and not waiting for the natural bone healing necessary for the complicated job of weight bearing and motions of the hip joint, as in walking and the like.

For the treatment of delayed union or nonunion of fracture at the neck of the femur, several types of subtrochanteric osteotomy are discussed with satisfactory solution of this problem.

CHARLES A. WATKINS, M.D.

McCarthy, P. V., and Van Demark, R. E.: March Fracture of the Inferior Pubic Ramus. *MH. Surg.*, 1946, 98: 233.

March fracture of the inferior pubic ramus is characterized by pain in the inguinal and perineal regions; the pain may also radiate to the knee. The pain in the knee is referred by way of the obturator nerves.

March fracture of the inferior pubic ramus usually occurs in persons who are not used to strenuous exercise and are suddenly subjected to it. Early diagnosis is based on clinical examination because the roentgenograms are of little value in demonstrating the fracture line, but as soon as callus has formed the roentgenograms will show a spindle type of callus formation around the fracture line.

The treatment is entirely symptomatic. Bed rest is not advisable. The 2 cases presented by the authors and the cases presented by Jones and Nickerson showed no untoward effects when treated ambulatorily. Most of the patients returned to duty after 4 months and had no complaints except occasional mild pain in the inguinal regions.

GEORGE I. REISS, M.D.

Foley, W. B.: Treatment of Slipped Upper Femoral Epiphysis. *Proc. Roy. Soc. M.*, Lond., 1946, 39: 201.

This article is the President's address to the Section of Orthopaedics of the Royal Society of Medicine. Concerning the etiology of slipped epiphysis of the upper part of the femur, confirmation of the observations of Howorth was made, i.e., the swelling of the synovial membrane seen at operation, the histological finding of a simple synovitis, the elevation of the blood sedimentation rate in early cases, and the constant appearance of juxtaepiphyseal decalcification in roentgenographs. However, the author is not inclined to accept entirely Howorth's proposal of an inflammatory etiology and suggests that except for the elevated sedimentation rate the findings might be due to traumatic synovitis and secondarily to the epiphyseal slipping rather than that they are the primary cause of it.

Since treatment is so much more satisfactory in early cases than in late ones, the cases are divided into two groups: (1) early cases with minimal epiphyseal displacement, and (2) cases with severe or complete displacement of the epiphysis. Group 2 may be divided into (a) acute cases with a short history usually including slight injury and symptoms and signs severe enough to suggest a fracture of the neck of the femur, and (b) cases with a long quiet history of increasing pain and deformity.

It is important to suspect this condition in any adolescent of either sex, between the ages of 9 and 18, who is complaining of limping or of pain in the hip and knee. Once the diagnosis is made or suspected all weight bearing should be forbidden absolutely, since if continued there is a grave risk that at any moment the case may pass from the favorable first group into the less favorable second group.

Excellent results are obtained by treating early cases by the insertion of a Smith-Petersen three-flanged pin across the epiphyseal line into the epiphysis without any preliminary manipulation or attempt at correction of the deformity, according to Wilson's technique. This technique was employed in 5 cases by the author with excellent results after a follow-up period that ranged from 1 year to 7 years. There was $\frac{1}{4}$ inch shortening in 1 case only and slight limitation of internal rotation in 3 of the cases.

In evaluating his results the author employs the term "excellent" in patients who are quite symptom free and have either no limitation of hip movement or a few degrees of limitation of internal rotation only. Roentgenography shows no deformity or evidence of arthritis. Patients having "good" results are leading lives of normal activity with no pain, or only an occasional ache with weather changes, but have definite limitation of internal rotation and possibly also of flexion and abduction. Roentgenography may show some deformity of the head and neck, but no arthritic changes. Patients classified as having "poor" results have pain and/or gross limitation of all hip movement and possibly some fixed deformity. Roentgenography in these cases shows evidence of avascular necrosis or of arthritis.

Eight cases of Group 2 (a) classification were treated by manipulative reduction accomplished by means of the Leadbetter maneuver. Three of the patients were subsequently immobilized in plaster and in the other 5 the reduced epiphysis was pinned. In the former group the follow up period ranged from 8 to 14 years with an average of 10 years, with 1 excellent and 2 "poor" results. One of the patients subsequently needed arthroplasty of the hip. The follow up period of the pinned cases extends from 1 to 7 years, averaging 5 years, with 2 excellent, 2 good, and 3 poor results. In summary, among the 8 cases there were 3 excellent, 2 good, and 3 poor results. One of the pinned cases with a poor result is described; in this case avascular necrosis of the head occurred. Since this complication may occur in from 25 to 30 per cent of the cases treated in this manner, it is the author's opinion that the method should be abandoned.

An alternative way of treating this group is by strong skeletal traction employing a Steinmann pin through the lower third of the femur. The patient may be placed on a frame or the affected limb suspended in a Thomas splint and weights up to 20 pounds used. This strength of traction should not be maintained longer than 14 days at the outside, as there is some risk of interference with the blood supply from continuous tension on the capsule. If strong traction fails to reduce the displacement within 14 days this can be effected by open reduction through the epiphyseal junction. In 9 cases treated by this operation the follow up period ranged from 2 to 7 years and the results were: excellent in 1 case, good in 5 cases, and poor in 3 cases. The 3 poor

results were due to avascular necrosis of the epiphysis which resulted in restriction of movement as seen in fibrous ankylosis, and in 1 case it was accompanied by pain of sufficient severity to make arthrodesis necessary.

If reduction by strong traction fails and if both closed and open manipulation are to be condemned because of the high percentage of poor results, it is suggested that light traction may be continued till the epiphysis is fused in the position of deformity. This may be corrected by wedge osteotomy of the neck of the femur or by subtrochanteric osteotomy. In 9 cases treated by osteotomy of the neck, 5 patients were immobilized in plaster following the operation, and 4 were pinned. The average follow up period of the 5 plaster cases was 8 years and the results were all classified as good. The follow up period of the pinned cases ranged from 1 to 3 years. One result was classified as excellent and the 3 other results were considered as good. The majority of these cases had some shortening, but in no case did it exceed an inch. Most of them had some limitation of internal rotation and in some cases of flexion and abduction as well. Restoration of mobility of the affected hip was much speedier and rather more

complete in the pinned cases than in those immobilized in plaster after operation.

Investigation of the results of subtrochanteric osteotomy was disappointing since a number of patients so treated were of military age and could not be located. However, it is the author's impression that subtrochanteric osteotomy gives a satisfactory result in most cases and delays, if it does not prevent, the onset of mechanical osteoarthritis by improving the weight bearing alignment.

Four cases treated by a short period of traction in bed, followed by the wearing of a caliper splint for a year or longer, or treated by means of a caliper splint only were traced from 16 to 23 years later. From the results it is concluded that hips treated conservatively without operation can function satisfactorily for as long as approximately 2 decades. The uncorrected deformity may exist for many years without roentgenographic evidence of arthritic changes. There must not be too vigorous an attempt to obtain anatomical perfection if it involves the risk of serious impairment of function.

Case reports and illustrative roentgenographs are included in the article and a short bibliography is appended.

CHARLES A. WALTMAN, M D

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Leriche, R.: Arterial Thrombosis. Experimental and Clinical Conditions (La thrombose artérielle, conditions expérimentales et cliniques). *Lyon chir.*, 1945, 40: 167.

The author reviews the mechanism of the coagulation of blood. All the factors necessary for coagulation are present in the circulating blood but normally intravascular coagulation is prevented by the constant secretion of heparin by the reticuloendothelial system.

Thrombosis is defined as intravascular coagulation, but whereas ordinary coagulation starts with a precipitation of fibrin, thrombosis begins with a conglomeration of platelets. Experimentally, thrombosis may be caused by slowing the blood stream at the site of a minor injury to the endothelium. Clinically, in human beings, however, this rarely causes the formation of a thrombus. The author mentions a case in which he had given 35 intra-arterial injections of mercurochrome with a tourniquet in place but there was no thrombosis. On the other hand, there are some individuals who develop extensive thrombosis with the slightest injury to a vein or artery. Apparently there is some unknown factor which predisposes to thrombus in certain people.

Thrombosis requires an endothelial lesion, but in most cases the obvious types of lesion are not apparent, e.g., gross trauma, and medial calcification. The author considers other factors. Infection including syphilis is rarely concerned. Some of the experimental work on the vasospastic effect of tobacco is reviewed, but the author finds it unconvincing. Exposure to cold, on the other hand, seems important. Patients who have had frost bite are prone to develop arteritis at an early age. Venous thrombosis is often followed by thrombosis of the adjacent artery. The loss of a large amount of blood frequently causes arterial thrombosis. It is suggested that the blood loss affects the viability of the intima, which in turn results in obliterative endarteritis. Yet, a sudden drop in blood pressure may precede thrombosis in apparently healthy arteries.

In addition to local factors, the author believes there may be an endocrine basis for arterial thrombosis. Experimental work would seem to incriminate the adrenals, gonads, and parathyroids, but the mechanism is still obscure. Arterial thrombosis is almost exclusively a disease of males. It is rare in negroes, and most frequent in Jews.

THEODORE B. MASSELL, M.D.

Leriche, R.: The Laws of Arterial Thrombosis (Les lois de la thrombose artérielle). *Lyon chir.*, 1945, 40: 477.

The time required for the organization of a thrombus varies according to the age of the individual, the

reparative power, and the state of the vessel lining. Calcium deposits, cholesterol, or fat crystals slow up the rate of organization. In some people there may be no signs of organization for many weeks. Experimentally, it has been demonstrated that with only a small area of intimal damage without infection the vessels that invade the thrombus will run parallel to the lumen of the thrombosed artery. If the parietal lesion is extensive and infected the vessels penetrate everywhere in a radial direction.

The author quotes Fontaine and Bauzen of Strassbourg who have formulated certain laws regarding the organization of arterial thrombosis:

1. The speed and the importance of the organization of the clot are in inverse proportion to the extent and the age of the endarterial lesions.

2. A decreasing significance of organization corresponds to an increasing significance of the endarterial lesions.

3. The organization of the clot occurs in a regular and essentially concentric form in young patients with arteritis, and in an irregular and diverging form in old arteritics.

4. The speed of organization of the clot is not so much a function of endarteritis or of the endothelial state as of the integrity of the media.

5. In aseptic thrombosis the new vessels are axial. In infected thrombosis they are radial.

The question is raised as to whether spasm alone can bring about thrombosis. While the author's clinical experiences have led him to believe it likely, he believes that this hypothesis cannot be definitely accepted without further investigation.

Whether a thrombosed artery is recanalized or not is of no functional significance. The author believes that a recanalized segment should be resected just as if it were completely obliterated.

The inflammatory reaction about a thrombus extends beyond the adventitia of the artery to the walls of the veins and the nerves which accompany it. However, an arterial thrombus rarely leads to a thrombosis of the vein, although the opposite process is frequent. Thus, the vein becomes adherent but not obstructed at the site of an arterial clot.

Upward extension from the site of arterial thrombosis tends to go to the first major collateral but may remain localized in a short segment. Distal extension occurs but slowly. Lumbar sympathectomy does not stop the extension of the clot but sometimes even seems to accelerate it. The only way to keep a thrombus localized is to excise it. Thrombosis does not seem to recur above a ligature.

Arteriectomy does more than stop the spread of a thrombus; it removes the vasoconstrictor impulses which arise from the thrombosed segment. By reducing the collateral circulation the vasoconstrictor effect of the thrombus is more important than the local arterial obstruction in causing ischemic gan-

grene. The author considers resection of the thrombosed segment just as effective as sympathectomy in achieving vasodilation of the collateral vessels.

If venous thrombosis occurs simultaneously along with arterial thrombosis the gangrene is fatal. It is massive and often of the wet variety.

Arterial thrombosis may be entirely silent and asymptomatic or it may cause extensive gangrene; this depends on the extent of the thrombus, the location in relation to the major collaterals, the presence or absence of hematoma and edema in the surrounding tissues, the degree of vasoconstriction of the collaterals, the presence of simultaneous venous thrombosis, and the adequacy of the general circulation. Treatment should be based on the knowledge and control of these various factors.

TREDOORE B. MASSELL, M.D.

Allen, E. V.: *The Challenge of Thrombosis and Embolism of the Blood Vessels, and the Clinical Use of Anticoagulants. Q Bull Northwest Univ. M. School, 1946, 20:1.*

The author traces the history of dicumarol. He states that as great a proportion of patients who are sick with "medical" conditions die from pulmonary embolism as the proportion who undergo operations. About half of all middle aged and older patients who have died after being in bed for varying periods of time have thrombosis of the deep veins of the legs. There is increasing evidence that bland venous thrombosis produces signs and symptoms which may be recognized easily by experienced physicians.

Because the effect of dicumarol is delayed, heparin must be used also when an effect on the coagulation of the blood is desired quickly. Fifty milligrams of heparin are injected intravenously every 4 hours until studies of the prothrombin indicate reduction to a satisfactory value (20%).

Since thromboplastins vary in potency, the prothrombin time should not be used as the basis for regulating dicumarol dosage. The prothrombin should be reported in the percentage of normal. This can be accomplished by a simple method. Normal plasma is diluted with a solution of normal saline solution to produce 90-80-70-60-50-40-30-20-10 per cent of the normal plasma. (The dilutions also represent the percentage of normal prothrombin.) Then the prothrombin time is determined for each of these dilutions. Thus, if the prothrombin time for 20 per cent prothrombin (normal plasma diluted 4 times) were 35 seconds, all prothrombin times of 35 seconds would indicate 20 per cent of normal prothrombin, provided the thromboplastin remained constant. After the prothrombin time for the various dilutions is determined (representing the percentage of normal prothrombin), a curve can be plotted which will indicate the percentage of prothrombin of any plasma for which the prothrombin time has been determined. This curve will allow quick conversion from prothrombin time to percentage prothrombin.

Attention must be given to the thromboplastic substances used, for they vary in potency, and iden-

tical prothrombin times for two lots of thromboplastin may indicate entirely different values for prothrombin (percentage of normal). When the Quick test for prothrombin time is performed repeatedly during treatment with dicumarol, either each batch of thromboplastin must be proved to have the same potency as the former, or a new dilution curve should be plotted for each new batch. The problem has been simplified by the observation that the critical figures in treatment with dicumarol are those representing 10 per cent, 20 per cent, and 30 per cent of the normal prothrombin. One may administer dicumarol adequately knowing only these figures, for clinical experience has indicated that intravascular thrombosis rarely occurs when the percentage prothrombin in the blood is less than 30, and bleeding rarely occurs when the percentage prothrombin is 10 or more.

Three hundred milligrams of dicumarol are given on the first day and 200 mgm. are given on the second day. On each subsequent day of therapy the percentage prothrombin is determined and reported. If the value is more than 20 per cent, 200 mgm. are given; if it is less than 20 per cent none is given. There are minor exceptions to this program. If the patient's blood is sensitive to the effect of dicumarol, only 100 mgm. may be given instead of 200 mgm. If the patient's blood is insensitive to the effect of dicumarol, 300 mgm. may be given instead of 200 mgm. If the percentage prothrombin is decreasing rapidly but is more than 20, no dicumarol is given. If it is rising rapidly, but has not yet quite reached 20 per cent, the drug is given on that day. Ordinarily treatment with dicumarol is continued until the patient has been ambulatory for about a week. The effect of dicumarol ordinarily continues for a few days after discontinuation of treatment. Of course, no protection is afforded against intravascular thrombosis when the prothrombin value for the plasma is between 30 per cent (approximation) and normal.

It was originally believed that vitamin K was ineffective in correcting prothrombin deficiency induced by dicumarol. It is now known that the amounts of vitamin K which were used were entirely inadequate. It has been shown that 64 mgm. of menadiol bisulfite (injected intravenously) corrected excessive prothrombin deficiencies. Transfusion of 500 c.c. of blood, preferably fresh, is also effective; it may need to be given once or twice daily until bleeding stops. If an emergency operation must be performed on a patient who is receiving heparin, the discontinuation for an hour or so will permit the blood to return to a normal state of coagulability. If an emergency operation must be performed on a patient receiving dicumarol, large amounts of vitamin K, and transfusions may be given to return the percentage of prothrombin toward normal values.

The author lists the indications for anticoagulant therapy.

1. After nonfatal pulmonary embolism to prevent further embolism which may be fatal.

2. For thrombophlebitis and phlebothrombosis to prevent further venous thrombosis and pulmonary embolism.

3. For sudden arterial occlusion (embolism and thrombosis) to prevent arterial thrombosis which results from ischemia of the intima (distal to the area of occlusion) and to prevent thrombosis of an artery at the site of embolotomy provided a surgeon removes the embolus.

4. For traumatic injury to the blood vessels to avoid thrombosis.

The author also gives the following possible indications:

1. Prophylaxis against postoperative venous thrombosis (dicumarol only) in cases in which venous thrombosis or embolism have occurred previously, because of the increased probability of further venous thrombosis or embolism.

2. After abdominal hysterectomy (dicumarol only); because 4 per cent of patients who have this operation have postoperative venous thrombosis or embolism and 0.7 per cent die of fatal embolism.

3. In myocardial infarction, congestive heart failure, and cardiac irregularities which predispose to embolism, for the purpose of preventing embolism. (The author has had no experience with patients with these conditions.)

4. Older patients who are confined to bed for long periods, because the probabilities of venous thrombosis and embolism are relatively great (dicumarol only).

The conditions in which anticoagulants are to be used cautiously or not at all are as follows:

1. In cases with vitamin C and K deficiencies or of profound liver disease with prothrombin deficiency, because anticoagulants probably are not needed, and use of them may magnify the tendency to bleed, and with disastrous results.

2. In cases of renal insufficiency because the effect of dicumarol is greatly enhanced by ligation of the ureters of dogs.

3. In cases of blood dyscrasia with impairment of the normal coagulation mechanism, because anticoagulants magnify the tendency to bleed.

4. In cases which have undergone recent operations on the brain or spinal cord, because bleeding in these areas may be disastrous.

5. In cases with ulcerative lesions or open wounds, because of magnification of the tendency to bleed.

THEODORE B. MASSELL, M.D.

BLOOD; TRANSFUSION

Levine, P., and Waller, R. K.: Erythroblastosis Fetalis in the Firstborn. *Blood, J. Hemat.*, 1946, 1: 143.

The authors note that as a result of studies of the pathogenesis of erythroblastosis fetalis, a new diagnostic procedure, testing for the Rh factor, has been made available. The findings presented indicate that future emphasis should be placed on the prevention of isoimmunization by transfusions in the

group of Rh negative female patients at any time prior to possible pregnancies.

Isoimmunization by the Rh factor occurs in two groups of cases: (1) Rh negative individuals after repeated transfusions of Rh positive blood, and (2) Rh negative women immunized by Rh positive fetal blood. A third group may be mentioned in which both factors, transfusion and pregnancy, are operative.

This paper deals mainly with selected cases of the third group in which isoimmunization was initiated by transfusions and, after a variable interval, became intensified through pregnancies. Evidence is presented which indicates that the combined action of both factors in the order given served to increase the number of infants with erythroblastosis fetalis as well as the severity of the condition in the infant.

Ninety two per cent of all cases of erythroblastosis fetalis result from (1) immunization of the Rh negative mother by Rh positive fetal blood, and (2) subsequent action of maternal anti-Rh antibodies on the susceptible Rh positive fetal blood. The obstetric histories of mothers of erythroblastic infants reveal that this condition occurs in the first born only very rarely. One or more pregnancies with Rh positive infants are required to induce a sufficient degree of isoimmunization. Once an Rh negative woman is immunized, each successive pregnancy with an Rh positive fetus results in increasingly severe forms of erythroblastosis fetalis.

In this study, limited to approximately 700 Rh negative women, only 28 instances were found in which the first Rh positive infant had erythroblastosis fetalis. Of these, 19 mothers gave histories of one or more transfusions at various times prior to the first full term, or almost full term pregnancy, and no such history could be elicited in a control group of 9 mothers.

The findings summarized in Table I seem to justify the conclusion that previous transfusions initiate isoimmunization, which is intensified by the first pregnancy.

Although histological evidence to support a diagnosis of erythroblastosis fetalis was frequently not available, the selection of the cases can now be accepted on the basis of serologic findings in Rh negative mothers who have been immunized, as indicated by the presence of agglutinins or blocking antibodies. These serologic tests were of particular value in cases in which autopsies were not performed or in which the tissues were too much macerated to permit histologic examination.

It is now believed that erythroblastosis fetalis occurs in about 1 of 150 to 200 random full term deliveries. This figure, based on Rh tests to detect all instances of isoimmunization, is to be contrasted with a value of 2 cases in 438 deliveries based on clinical grounds only. If all Rh negative women responded readily to isoimmunization, one should expect erythroblastosis fetalis to occur in almost all of the 13 per cent of matings in which the father is Rh positive and the mother Rh negative. At the same

time, erythroblastosis fetalis in the first full term Rh positive infant should occur very frequently.

As the authors noted, it is not possible to obtain a history of intramuscular administration of blood, but in view of its routine indiscriminate use in the past, this procedure must be considered as a possible source of the immunization of Rh negative individuals even in infancy or in the neonatal period. While infants do not produce antibodies as readily as adults, these intramuscular injections may at least serve to initiate the process. In short, it is advisable to avoid this form of therapy in Rh negative women unless Rh negative blood is used.

It is not generally appreciated that the degree of isoimmunization required to induce symptoms of hemolytic disease in the infant is far more intense than that required to produce a severe hemolytic reaction in the mother following the transfusion of Rh positive blood. Now that the pathogenesis of erythroblastosis fetalis is established, it is obvious that the hemolytic disease is the result of prolonged intra-uterine action of maternal anti-Rh agglutinins on the susceptible fetal blood. One may expect to find instances of Rh negative women with anti-Rh antibodies who nevertheless have normal Rh positive children, while in the following pregnancy the degree of isoimmunization is sufficiently severe to produce the hemolytic disease.

When the clinical importance of the Rh factor was established, emphasis was placed on the prevention

of intragroup hemolytic transfusion reactions by the use of Rh negative donors for all Rh negative patients already immunized either by previous transfusions or by pregnancies. Now, however, emphasis should be placed on the prevention of isoimmunization.

The deliberate isoimmunization of the Rh negative female population, even as infants, by transfusion or perhaps even by intramuscular injection of Rh positive blood, can now be prevented. This simple measure should, by itself, reduce the incidence of erythroblastosis fetalis, especially in its more severe forms.

The fundamental fact is that once an Rh negative individual is immunized, he or she must be considered as remaining potentially immunized for the remainder of his or her natural lifetime.

In conclusion, the authors note that the incidence of fatal forms of erythroblastosis fetalis in the first-born can be diminished by the simple measure of transfusing all Rh negative female patients, even as infants, with Rh negative blood. Once a female patient is found to be Rh negative, all subsequent transfusions must be carried out with Rh negative blood.

Present indications are that sufficient human anti-Rh serums will become available for the more extensive Rh tests required for the prevention of isoimmunization by transfusion.

HERBERT F. THURSTON, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Cossio, P., and Berreta, J. A.: Anticoagulant Medication with Dicoumarin (La medicación anticoagulante con dicoumarin). *Sem. med.*, B. Air., 1946, 53: 329.

Lack of experience in Argentina with dicoumarin has induced the authors to report their results in 6 cases treated in private practice and in 10 hospital patients. The preparation was administered orally in doses of 300 mgm. on the first day and 200 mgm. on the second. Dosages during the following days depended upon the results of the tests for the prothrombin time (which should be done daily), but were usually from 50 mgm. to 100 mgm., when the tests showed a prothrombin which was 25 per cent above normal. There were no harmful effects, save for infrequent hemorrhages due to excessive dosage. Hemorrhage occurred in only 1 patient in this series, with a bacterial endocarditis and a prothrombin time which had been reduced to 5.5 per cent, and disclosed hemorrhage into the third and fourth ventricles together with small hemorrhagic foci in the kidneys and lungs. The authors state that the time and is of fresh blood reduces the thrombotic complications of prothrombin medication. Vitamin K is efficacious in this regard and must be employed in massive dosages by injection. Of the 16 cases reported, 7 were diagnosed as subacute endocarditis, and in these the dicoumarin was usually employed in combination with the sulfadiazine and penicillin. The authors do not claim any marked benefit from the anticoagulant therapy—although the combination did seem to benefit the patient in a few instances. However, it was in several instances in which a thrombosis of the bottom of the trouble that the most striking beneficial effect from the anticoagulant was observed; the first patient had a concomitant heart condition and died from this later. However, in the meantime the migratory phlebitis had entirely disappeared under immobilization of the affected extremity and administration of dicoumarin by mouth. The phlebitic process in another patient was not entirely controlled by the sulfadiazine or penicillin, but when dicoumarin was added the painful hardened veins disappeared and the patient could finally be up and about with only a small amount of edema around the affected ankle.

An interesting case of cardiac asthma with electrographic findings of infarct of the anterior wall of the heart was observed; dicoumarin was administered with the aim of preventing the development of a mural thrombus and apparent benefit resulted. In

another instance with electrographic findings of acute involvement of the pulmonary side of the heart, the attacks ceased permanently after treatment. In a patient with syphilitic aortitis with subsequent peripheral thrombophlebitis and pulmonary infarct the fever disappeared after a couple of days following dicoumarin treatment and the patient has remained well now for 2 months. In a woman who had undergone a subtotal hysterectomy for myoma, a thrombophlebitis in the left internal saphenous vein with fever, pain, and edema of the extremity developed after she had been on her feet for some time; sulfadiazine brought about some improvement but when combined with dicoumarin the symptoms disappeared in dramatic fashion. Much the same experience was encountered in a postoperative thrombophlebitis following a subtotal gastrectomy. The authors have not been able to affect the prothrombin time with dicoumarin administered per rectum.

JOHN W. BRENNAN, M.D.
Cannaday, J. E.: Cutis Graft in Surgery: A Review of Results Obtained, with Comments on Indications and Technique and a Report of Cases. *Arch. Surg.*, 1946, 51: 286.

The author reviewed 129 cases in which cutis grafts were used by himself and his associates at the Charleston General Hospital, Charleston, West Virginia, and was impressed by the field of usefulness of the cutis graft. The special merits of cutis as a repair material seem to be its pronounced tensile strength and freedom from the tendency to split; it becomes vascularized quickly, and it is gradually transformed into fibrous tissue, and it is gradually made use of cutis tissue whenever and wherever he would formerly have used fascia lata, and has obtained, in his opinion, superior results. With regard to the technique, the donor area is prepared with soap and water followed by alcohol and sterile dressing on the day prior to operation. Shortly before operation an iodine-alcohol preparation is carried out. After a thin epidermal layer is shaved away and the cutis area needed is outlined with a scalpel, the cutis edge is picked up with a sharp cutting with a short, curved pair of scissors. Approximately two or three Allis forceps are used with a fatty tissue is allowed to remain on the under surface of the graft. When a strip of cutis is secured for suspension of the cervix, thick cutis is secured for thigh, as cutis narrows greatly when put on the anteroexternal surface of the graft in position under the aponeurosis of the external oblique muscle when reinforcement seems indicated. When cutis is used as suture material,

the author believes it can best be handled with a moderately curved hemostat. The author, finally, uses the removed epidermal layer as a split thickness graft to cover areas from which a cutis graft has been removed. He believes this method is more satisfactory than the undercutting of skin edges to cover the donor area.

The surgical indications for this method of grafting as advocated by the author are: the treatment of incisional hernia, and stage operations in cases of strangulated hernia when the patients' condition does not permit repair of the hernia at the time the strangulation is released, the suspension of the uterine cervix, the ligation of large blood vessels such as the aorta, the reinforcement of certain types of aneurysm, the reinforcement and replacement in the repair of ruptured ligaments of the knee, and chronic recurrent dislocation of the shoulder joint.

The operative mortality was 2.32 per cent and the recurrence rate of hernia 3.2 per cent. There were 2 cases of rather serious wound infection, but the graft was lost in only 1. DAVID H. LYNN, M.D.

Gortchakoff, A. L.: The Treatment of Shock with Serum from Patients with Hypertension. *Vrachebnoe Delo*, 1945, p. 519.

There is experimental and clinical evidence that blood of patients with essential hypertension contains neurohumoral hypertensive substances which stimulate cardiac activity and raise the blood pressure. They exist in the blood a long time before the appearance of the clinical picture of hypertension.

The author studied the effect of serum obtained from patients with hypertension on the isolated hearts of cats and rabbits. Contrary to normal serum, the serum of hypertensive patients markedly increased the cardiac activity. In addition to tachycardia there could be observed an increase of the amplitude of the cardiac contractions up to 400 per cent. Serum from patients with climacteric hypertension had the greatest effect, while serum from patients with hepatic or so-called toxic hypertension had a depressing effect on the cardiac activity.

The next series of experiments was performed on dogs in which peptone shock had been produced. As a rule, the primary fall of the blood pressure was followed by its elevation and the animals perished after the second fall of blood pressure developed. The intravenous introduction of normal serum was not able to prevent the death of the animals, but 3 c.c. of serum from hypertensive patients per kilogram of body weight prevented death in nearly every experiment. Similar results were obtained after a suboccipital introduction of serum.

In another series of experiments traumatic shock was produced either by contusion of the soft parts of the thigh, or evisceration and hammering of the mesentery of the small intestine. While all of the control animals perished, 50 per cent of those which were given serum from hypertensive patients survived the experiments. In another series of experi-

ments the trauma of the mesentery in dogs was preceded by the administration of thyroxin with adrenalin in order to accelerate the appearance of shock. Intravenous administration of the serum from hypertensive patients saved 50 per cent of the animals, while the suboccipital mode of administration failed completely. JOSEPH K. NARAZ, M.D.

Varco, R. L.: Preoperative Dietary Management for Surgical Patients. *Surgery*, 1946, 19: 303.

This article, the author's thesis for the degree of Doctor of Philosophy, deserves particular attention. Not alone is its literary style unique but the entire problem of preoperative dietary management for surgical patients is evaluated in a scholarly manner. Unquestionably, in part at least, this is due to the fact that emphasis is shifted to include an orientation in the biological sciences included in a surgeon's graduate training. Until recently, accomplishments in dietary care have lagged disproportionately as compared to other progress in the realm of surgery.

A broad zone exists between optimal nutrition and classical deficiency states, and alertness is necessary in order to detect instances of occult inanition. During semistarvation or starvation states, a man survives at the expense of his bodily substance, and suffers from the compound evils of a low protein and high fat diet. Eventually this may evoke hepatic dysfunction, a fatty liver, and hypoproteinemia, which states, if not properly combated, lead to tragedy following surgical manipulations even of minor degree. The mere restoration of water and electrolyte equilibrium and the concurrent adjustment of the hemoglobin to a satisfactory value do not entirely obviate the hazard of subjecting a patient with considerable weight loss to a formidable operative procedure.

Certain aspects of the related literature, dating back to the experiments by Bernard in 1845, are examined and the salient features discerned. This serves to bring into bold relief the role which carbohydrates and proteins, in particular, play in potentiating natural hepatic resistance to deleterious agents. Anoxia is stressed as the causative factor of hepatic dysfunction in the instance of a fatty liver, and it is pointed out that these pathological states are labile and can be reversed under appropriate care.

The author then discusses hypoproteinemia in detail from the standpoint of its genesis as well as of its role in some complications which follow surgical measures. When hypoproteinemia is associated with edema, deliberate development, judiciously extended, of a mild state of dehydration and detoxication is advised. Our present knowledge as to the fate of ingested protein is reviewed and we are reminded that protein deposition and positive nitrogen balance cannot be obtained unless every essential amino acid is provided.

Therapeutic problems initiated by starvation states are broad and touch on many aspects of the surgeon's sphere of activity. Starvation pyramids

the hazards of surgery, but if good dietary preparation has been achieved, poor risk patients can withstand procedures of almost any magnitude as well as patients in good condition.

From much animal experimentation, diets were prepared which were rich in protein and carbohydrates but reduced in fat content. The author discusses in detail the various diets employed, two of which were administered most frequently. The subject of parenteral alimentation is also well reviewed, particular stress being placed on obtaining a positive nitrogen balance through the agencies of plasma, blood, and amino acids. Nor has the subject of intranasal gastric decompression and feeding been neglected. The instillation of a saline solution of human thrombin into a completely obstructed, bleeding stomach yielded encouraging results.

The author believes that the percentage weight loss is the most important and reliable single criterion by which one can judge the length of time each patient should be prepared nutritionally before operation, although, admittedly, this method is not precise.

DAVID H. LYNN, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Puckett, W. O., McElroy, W. D., and Harvey, E. N.: Studies on Wounds of the Abdomen and Thorax Produced by High Velocity Missiles. *Mil. Surgeon*, 1946, 98: 427.

To investigate the mechanism of wounding by high velocity missiles, the authors have taken high speed motion pictures (from 1,800 to 2,880 frames per second) and microsecond roentgenograms of living cats under nembutal anesthesia during the passage of a particle through the abdomen or thorax. In several instances the alimentary tract was visualized by giving a barium meal before the experiment. The missiles used were $\frac{1}{32}$ inch steel spheres (mass 0.130 gm.), with impact velocities of 3,200 feet/second, 22 caliber long ammunition (mass 2.62 gm.), and small fragments of 75 mm. shells.

In abdominal wounds produced by high velocity missiles the high speed motion picture studies showed a marked swelling of the abdomen just after entrance. This was interpreted as the development of a large temporary cavity within the abdomen and it persisted from 1.5 to 2 milliseconds. Following this the abdomen underwent a marked constriction, but again expanded, the second time more slowly. These changes in the abdominal cavity volume are purely physical and have no relation to muscular contractions which occurred much later. Comparing pictures of a water filled inner tube during the course of a high velocity particle through it, it was concluded that the abdomen behaved in the same manner as a liquid filled system. These experiments confirmed the earlier work of Callender and French who made observations and pressure measurements on water filled tin cans traversed by high velocity bullets. The phenomena produced were in propor-

tion to the striking energy of the particle, which is determined by its weight and velocity.

Roentgenograms of the abdomen showed that a large temporary cavity was formed immediately after entrance of the abdominal cavity by a missile. By outlining the intestines with a barium meal, it was demonstrated that loops of the intestine were widely separated during passage of the missile and the intestines were flattened by the expanding cavity. The intestines and stomach were altered in shape even some distances from the limits of the temporary cavity. Often the intestine appeared punctured in several places.

Irregular fragments fired into the abdomen varied in several respects. Since the amount of energy imparted to the tissues depends on the cross sectional area of the missile, a large surface causes the missile to give up its energy in a relatively short space rather than to disseminate it equally throughout the entire course. The irregular fragment also changed its course frequently in its passage through the tissues.

Autopsy studies on these abdominal wounds showed the external wounds produced by the spherical missiles to be small, while those made by the irregular fragments were more severe. Internal damage was out of proportion to the small perforations of the body wall. Tears as large as 4 by 6 cm. were frequently found in the mesentery and the cavity was filled by blood if vessels had been severed. Often multiple perforations of the intestine were found at points distant from the missile track. The general effect was that of an explosion taking place within the abdominal cavity.

With respect to thoracic wounds it must be observed that, unlike the abdomen, the thorax is anatomically rigid and air filled in contrast to the soft elastic fluid filled abdominal cavity. High speed motion pictures of the thorax during the passage of a high speed velocity missile showed very little movement of the thorax. Pronounced bulges at points of entrance and exit appeared, but these were limited to the soft tissues and no pronounced volume changes could be seen. Cavity formation would not be expected to be as great in an air filled medium and this is helped by the rigidity of the bony structure. Roentgenograms were not too successful because of the relative radiopacity of the chest structures with the exception of the heart. The heart was temporarily displaced, but no definite cavity was noticed. Autopsy examinations showed that external thoracic wounds tend to remain patent rather than to collapse as the abdominal wounds did. No fractures of ribs occurred at any distance from the missile track although the ribs directly in its path were badly broken. Varying amounts of blood were present according to whether or not major vessels had been injured. The lungs were greatly collapsed, much more so than is usual after a pneumothorax. Although tissue immediately on or adjacent to the path was badly damaged, the residual permanent cavity was never large. This was probably due to

the relative elasticity and sponginess of the pulmonary tissue.

In regard to the physical action of high velocity missiles traversing the abdominal and thoracic cavities, it must be remembered that any high speed particle passing through a medium imparts a certain amount of its energy to that medium and causes it to move away from the missile track. This radial displacement of the medium causes the formation of a rapidly expanding cavity immediately behind the missile which contains a negative pressure. When the tissue inertia is overcome, the external atmospheric pressure responds by collapsing this cavity completely and constricting the abdomen. This is followed by a second bulging of the abdomen of longer duration, but of less intensity. These are essentially the reactions of a fluid filled rubber tube or water can to a high speed particle. The formation of the large temporary cavity results in rapid pressure changes in the adjacent areas. The first of these, the "positive pressure pulse," is of short duration, no longer than $\frac{1}{4}$ millisecond. Because of the heterogeneity of the tissues within the abdominal cavity, actual records made by piezoelectric crystal gauges show several pressure peaks rather than a single one as is observed in water filled tubes and cans. Because of the rapid radial displacement of tissues about the missile course, secondarily there is a period of negative pressure in the medium about the cavity. This period of lowered pressure may have serious effects on the tissues. Gas masses increase in volume and multiple perforations of the intestine are probably due to this. To investigate this, a ring of cat colon was filled with saline solution and placed in a tank of saline solution. Two bubbles of air were injected into the colon. A high speed bullet was fired through the ring and motion pictures were made. At first there was a slight constriction of the air bubbles, only to be succeeded by a marked swelling of the intestine in the region of the bubbles. Rapid pressure changes are important factors in producing wounds.

In summary, the following phenomena occur in abdominal and thoracic wounds produced by high velocity missiles. The abdomen swells immediately after the passage of a missile. This persists for 1 or 2 milliseconds and is followed by a constriction lasting 4 or 5 milliseconds. This is succeeded by a second bulging of the abdominal walls of greater duration, but less intensity. These movements are dependent for their rate and magnitude on the striking energy of the particle. Coincident with the initial abdominal expansion there is a large temporary cavity inside the abdomen. Internal damage to the viscera is far out of proportion to the wounds of exit and entrance. The general effect is that of an explosion within the abdomen. Irregular missiles vary their behavior in accordance with the projected area as they strike. No volume changes occur within the thorax. This is due to the rigid skeletal thoracic cage as well as to the contained air.

C. FREDERICK KITTE, M.D.

Cameron, G. R., Allen, J. W., Coles, R. F. G., and Rutland, J. P.: Acceleration of Healing by Pressure Application to Experimental Thermal Burns. *J. Path. Bact.*, Lond., 1946, 58: 1.

The prompt application of pressure bandages to thermal burns of the extremities of goats accelerates the rate of healing and greatly reduces the mean healing time. The pressure interferes with the effusion of plasma and the formation of fibrin at the burn site decreases the amount of reparative tissue, and probably decreases the chance of local infection.

Pressure should be applied as soon as possible after burning to get the best results. A delay of 4 hours is probably the limit for beneficial effects.

There is no need to maintain the pressure application for much longer than a week, for there is very little difference in mean healing times of standard burns treated with pressure for 9, 16, or 30 days. Removal of the pressure bandages during a critical phase lasting for several days after burning is followed by severe edema of the burned area and delay in healing.

SAMUEL KATZ, M.D.

Pavlovsky, A. J., Oghl, A., and Harris, M. M.: The Sequelae of Burns; Treatment with Skin Grafts (Quemaduras; sus secuelas; tratamiento por los injertos libres de piel). *Rev. As. med. argent.*, 1945, 60: 78.

Some raw surfaces resulting from burns have been treated by means of skin grafts. Two types of cases are considered: the immediate, presenting a loss of substance, and the late, presenting keloid and scar formation.

Raw surfaces are generally not treated by grafting early unless the receptive wound is clinically prepared to receive the graft, as the chances of failure are great. A wound covered with flat, granulation tissue without active bleeding is the most favorable for grafting, otherwise this procedure is contraindicated.

Bacteriological studies were omitted in as much as practically all plastic surgeons agree that absolute sterilization is almost impossible and that wounds covered by adequate granulation tissue are favorable to grafting even in the presence of mild infection. Daily treatments with gauze impregnated with cod liver oil were made, and alternated with the application of sulfonamides for a period of 2 days. When the wound was ready, saline dressings were applied. As a rule, granulation tissue was curetted during the operation except in the cases in which the wound was greatly infected and responded poorly to the treatment as outlined. Preference was given to the sulfonamide compounds which incorporated "allantoin" in powder or ointment form.

The treatment of the late sequelae of burns consisted of the removal of all scar tissue interfering with free motion of the parts involved and until sound tissues were encountered. Only the most important vessels were ligated and sutures were used sparingly to avoid foreign body reactions. The resulting wound is generally ready for grafting.

at once; otherwise it is powdered with sulfonamides and covered with aseptic gauze. At the end of from 6 to 8 days the wound is ready for grafting.

Donor areas are generally selected from the anterolateral aspect of the thigh inasmuch as technically it is the best location for obtaining thin grafts. This location has not, however, been satisfactory because such areas frequently become dark in color and even may form keloids. At times, grafts have been obtained from the buttocks. Better epithelialization takes place in spite of the supine position. At any rate, if there is keloid formation the area is a concealed one. Once the graft is obtained, the donor area is covered with saline dressings after it is powdered with sulfonamides. As a rule, from 12 to 15 days later the area is healed.

The grafts have always been obtained by means of the Padgett's dermatome or a copy of the original. A liquid preparation made by Dunlop mixed with a third of its volume of ether just before it is applied has been used as an adhesive. The impression has been gained that the preparation is more adherent when used this way.

The use of small sutures to fix the graft has been given up and the procedure used by M.E. Sano (*Surg., Gyn. Obst.*, 1943, 77:510) has been adopted. The plasma and thrombin extracts were obtained by the authors from the patient's own blood.

With the help of a camel's hair brush, plasma is spread over the wound, and the graft is spread with thrombin extract while it is still adherent to the dermatome. The authors believe that the results of the method have been satisfactory and intend to try the method further. They believe that both thin and thick grafts take well but prefer the relatively thick ones (from .6 to .8 mm. thick) because the thin ones have a tendency to develop phlyctenular areas which become infected later.

F. F. REMY, M.D.

Gordon, J., Hall, R. A., Heggie, R. M., and Horne, E. A.: A Histological and Bacteriological Study of Healing Burns with an Inquiry into the Significance of Local Infection. *J. Path. Bact.*, Lond., 1946, 58: 51.

A small series of second and early third degree burns has been examined in detail, with the method of biopsy to assess the extent of the initial injury and to determine the mode of healing.

Epithelialization of second degree burns takes place multifocally from the viable epithelial cells lining the sweat ducts and hair root follicles. There appears to be no latent period during this process.

In pure second degree burns healing can occur in the presence of the hemolytic streptococcus and the staphylococcus aureus, singly or together, with little if any retardation.

If infection becomes established in the third degree areas of mixed second and third degree burns, the healing of the neighboring second degree areas is quite frequently delayed.

JOHN J. MALONEY, M.D.

Saarenmaa, E.: On Clostridia Infections in War Wounds on the Karelian Isthmus. *Acta chir. scand.*, 1946, 93: 363.

The observations, presented by the author are based upon experiences in field and evacuation hospitals during the wars on the Karelian Isthmus between 1940 and 1944. Clinically, no cases of gas edema involving the head, throat, chest wall, or upper extremities were observed. In the lower limbs, however, numerous gas-containing infections appeared in connection with traumatic ischemia. Only in 2 rapidly fatal cases, not studied bacteriologically, was the site other than the lower extremities. In one of them gas infection resulted from a splinter penetration of the lung tissue and produced "pressure pneumothorax"; in the other, gas edema developed in the abdominal wall after an operation for a wound in the abdomen. No division into "brown" or "blue" forms of gas edema was observed. From August, 1944 to the Armistice, gas-containing wound infections were examined bacteriologically in 5 cases and in all of them the pathogenic clostridium was found. Specimens were taken through undamaged skin from gas-containing tissues. In 3 instances the infection was monomicrobial.

The case reports cited are examples of three different types of disease: (1) a case of empyema due to clostridium septicum in which pressure pneumothorax developed and recovery followed operation; (2) gas edema due to the clostridium welchii and a strain not closely identified, and contusion of the muscle tissue (2 cases); and (3) far advanced gas edema due to the clostridium welchii affecting the lower extremities in which traumatic ischemia was simultaneously present (2 cases); immense gas edema at the site of a splinter embolus in a posterior tibial artery as the result of a splinter which entered the left axilla and penetrated the lung tissue and the left ventricle of the heart (1 case which terminated in death). Except in combination with traumatic ischemia, malignant gas edema was very uncommon on the Karelian Isthmus.

Traumatic edema must be considered the most important predisposing cause of gas edema. This should be kept in mind when plaster dressings and tourniquets are applied as they may cause the gas edema to break out when the virulence of the clostridia is slight. Gas edema may occur in mild forms as shown by the presence of pathogenic clostridia and histolysis of muscle. Whether routinely administered tetanus antitoxin contributed to a decrease in virulence is uncertain. In the diagnosis, roentgenograms aid in the differentiation between the gas edema, gas abscess and gas-containing phlegmons.

WALTER H. NADLER, M.D.

Kogan, I. S.: The Therapy of Infected Wounds and Acute Infections with Immunotransfusions. *Vrachebnoe Delo*, 1945, p. 147.

The author describes immunotransfusions as a method of active stimulation of the mesenchyma of the reticuloendothelial system. The treatment

should be instituted as soon after infection has occurred as possible, especially if the wound is extensive and soiled. Wright introduced the method of immunotransfusion in 1919 for the purpose of raising the resistance of the body by passive immunization.

The author studied the possibility of not only antimicrobial but also antitoxic and mixed immunity. He accumulated experimental and clinical evidence that it is possible within 3 days to create a marked increase of immune bodies in the donor's blood and to preserve them for from 10 to 12 days. The increase of immunity may last a month if a prolonged method of immunization is used.

A diminution of the minimal osmotic resistance of the erythrocytes may be considered as an index of an intensified production of young erythrocytes. Conversely, an increased maximal resistance of the erythrocytes indicates an aging process of the blood. According to the author's observation, immunotransfusion was followed by a fall of the minimal resistance of erythrocytes, which demonstrated the stimulating effect of the transfusion.

Increase in the number of thrombocytes, demonstrating a stimulation of the bone marrow, was one of the results of immunotransfusions.

The author performed a sternal puncture on 25 patients with various septic, suppurative processes and found that immunotransfusions were followed by a stimulation of erythropoiesis or, less frequently, leucopoiesis. The number of cells of the erythroid group increased, while the number of the least ripe myeloid cells and plasma cells diminished.

The index of cellular and humoral immunity increased following immunotransfusions. This observation also demonstrated the stimulation of immunogenesis in patients with septic conditions. The number of phagocytes, the opsonic index, and the agglutination titer were determined in order to study the effect of immunotransfusions.

The dynamics of reticulocytosis were studied in patients with septic conditions before and after immunotransfusions because reticulocytosis serves as an index of the intensity of the regenerative processes, especially medullary erythropoiesis. As a rule, the number of reticulocytes increased following immunotransfusion.

The functional condition of the reticuloendothelial system may be evaluated by the study of histiocytosis. The author studied lymphohistiocytosis before and after immunotransfusion in blisters produced by cantharides. A definite relation between the immunobiologic, reactivity of the organism and the intensity of proliferation of histiocytic formation definitely exists. The author's observations demonstrated the stimulating effect of immunotransfusion which was followed by an increased number of lymphohistiocytes. The author's observations on more than 500 patients definitely established the stimulating effect of immunotransfusion. A passive immunity may be produced in the recipient by the transfusion of blood from an im-

munized donor. The passive immunity lasts approximately 3 weeks. The transfused immunized blood acts as a stimulus for immunogenesis in the recipient. The immunized blood, more saturated with proteins than the regular blood, produces a more intensive colloidalolysis. The bactericidal power of the blood and tissues rises under the influence of immunotransfusion. Finally, the immunized blood diminishes the allergy of the organism.

JOSEPH K. NART, M.D.

Hudson, R. V., Meanock, R. L., McIntosh, J., and Selbie, F. K.: Penicillin Therapy: Clinical and Laboratory Observations of 400 Cases. *Lancet*, Lond., 1946, 1: 409.

Of the 400 cases reported, 20 were severe injuries in which the penicillin was used as a prophylactic agent; 380 were cases of acute or subacute established infections. Two hundred and forty-two patients were treated with systemic, 46 with systemic and local, and 92 with local penicillin. Of the 388 cases treated with systemic penicillin, 368 were surgical and 100 medical infections.

In the surgical group there were 8 failures and 11 deaths; in 162 patients, an apparently complete recovery was obtained, while in 7, the acute lesion was reduced to that of a chronic infection.

In the medical group, there were 6 apparently complete recoveries, 11 deaths, and 15 failures. The deaths were due to the severe complications present at the outset of treatment, or to underdosage.

Actinomycosis and persistent infections of the deeper tissues of the eye proved most resistant to treatment. In systemic therapy a dose of 60,000 units, injected intramuscularly every 3 hours during the day and night, was found to be the most satisfactory. The duration of treatment varied from 1 to 28 days.

In traumatic surgery, the extirpation of avascular tissue was essential to penicillin therapy.

In established infections, of the several methods tested, two proved satisfactory. When penicillin had converted the acute lesion to a chronic one, a small incision and temporary drainage were all that was necessary or advisable in the majority of cases, but in a minority of the cases, and for specific reasons, the radical removal of all visibly infected material, followed by primary suture and temporary drainage, gave uniformly satisfactory results. Whichever method was employed, it was essential to continue penicillin for a time long enough to control the residual infected tissue.

Local administration was valuable in surface lesions; with local therapy, 61 patients were cured and 23 were not benefited. In all other infective lesions, systemic therapy proved the most satisfactory method, and, with the exception of meningitis and possibly empyema, supplementary local penicillin therapy was unnecessary.

Penicillin therapy has been a particular advance in the control of infections with staphylococcus aureus, streptococcus viridans, and the sulfonamide-

resistant gonococcus. The successes obtained have been due to maintaining a concentration in the tissues of sufficient strength and for sufficient time to enable the patient to utilize his natural defenses to the full. An apparent cure has been obtained in cases in which the patient has been able to localize his infection so that he can absorb necrotic tissue, spontaneously extrude pus or dead tissue, or provide safe conditions to enable the surgeon to assist recovery by removing dead tissue.

WALTER H. NADLER, M.D.

Twining, H. E., Dixon, H. M., and Weldman, F. D.: Penicillin in the Treatment of Madura Foot; Report of 2 Cases. *Nat. Med. Bull.*, 1946, 46: 417.

Two cases of madura foot are reported. In both cases the disease was contracted outside of the tropics. The fungus species concerned were among the rarer causes of madura foot—the monosporium apiospermum and the cephalosporium granulomatis.

The results of penicillin therapy differed in both cases. In one, the disease had progressed to the development of osteomyelitis and, although an apparent cure was achieved at first, relapse occurred and amputation had to be done even though the penicillin was administered over a relatively long period of time (27 days). In the other case only the soft tissues were involved, and at the end of 8 months the cure appears to be permanent.

Although there appears to be a parallelism between madura foot and actinomycosis, in regard to the possible value of penicillin therapy, no generalization can be made at the present time. Certainly, it cannot be made to include the entire group of deep mycoses, in view of the recalcitrance of coccidioid granuloma and histomycosis. It is even unreasonable to expect penicillin to be uniformly efficacious in madura foot, since this condition is a cloical entity in which no less than 8 genera and 30 species of fungi have been listed. The value of the penicillin will depend on the causative agent in each case. The necessity for precise mycological determinations in future studies of the value of penicillin in madura foot is, therefore, evident. SAMUEL KAHN, M.D.

ANESTHESIA

Tainter, M. L.: The Frontiers of Anesthesia. *Anesthesiology*, 1946, 7: 132.

There are two ways in which medical developments come into practical acceptance. The first unspectacular but perhaps quantitatively most important method is the continuous slow accumulation of bits of knowledge which insensibly modify the current practices day by day. The other type of progress is discontinuous, with a slow accumulation of disconnected and uncorrelated facts. Suddenly a dramatic incident fires the imagination and there is a rush to translate this dammed up store of knowledge into an entirely new concept of practice.

So it was with anesthesia at the time we consider the period of its discovery. Probably there were

numerous other experiences in the production of anesthesia, but these went entirely unnoticed for the lack of sufficient enthusiasm and of the prepared mind.

The antagonism to the then new procedure reveals the resistance which a valuable new concept oftentimes has to overcome before it gains general acceptance.

There have been many episodes similar to this in which sudden realization of the significance of a phenomenon, previously known to many, has resulted in an abrupt change in some phase of medical practice.

We are all on the frontier of medical progress. The time when a new frontier is to be crossed is largely up to our research scientists, but it also devolves on others to play their roles by seizing on new information and transforming it into practical clinical reality.

In recent times there has been renewed interest in the development of anesthetic agents of increased potency which might have an increased margin of safety. In the field of general anesthesia there are many desiderata which can be hoped for. A gaseous agent, of high potency, which is nonexplosive and with the predilection for depressing the neuromuscular system more than the sensory apparatus is desirable. The new ideal anesthetic would have no power to increase the irritability of the heart. Another field of development which needs more extensive exploration is that of intravenous anesthesia. There is no reason why, if the anesthetic agent has a short enough duration of action, it might not be possible to control anesthesia administered intravenously as flexibly as is now the case with gas anesthesia. We know now that certain substances protect the liver from damage by fat soluble materials, such as chloroform, and that procaine could be used intravenously to minimize the possibility of acute cardiac failure.

In the field of topical anesthesia, an anesthetic is needed which passes more readily through the surface to get at the nerve endings beneath. Such an agent should not be unduly irritating to the tissues locally or hazardous after systemic absorption. Another need is for a local agent which will penetrate the unbroken skin. An incompletely explored approach to this problem is possible with the use of new synthetic vehicles which may lead to increased penetrating power.

Fifty years of research have not succeeded in the creation of a local anesthetic capable of displacing procaine from the dominant position it holds as an injection agent. We need an agent which will produce prompt anesthesia at lower concentration without an increased toxicity proportionate to the greater anesthetic potency. Longer duration of the anesthesia is always a desirable property. Another desideratum for a spinal anesthetic solution might be "diminished diffusibility." The role of vasoconstrictors has not been adequately explored. Attention might also be directed to developing an antidote for the local anesthetic whereby the anesthesia could be

terminated at will. The optimal anesthetic solution for the use of caudal anesthesia in obstetrics has not been developed despite intensive studies.

There would seem to be a very definite field for the development of new analeptic drugs which have the power of stimulating the respiratory mechanism without risking at the same time the potentiality of convulsive after effects. The need is for a compound which does not cause increased utilization of oxygen by the tissues.

A relative of epinephrine—*ethylorsuprenen*—is worthy of considerable study in the field of resuscitation of the circulation as it has the power to augment the force of contraction of the heart, but dilates the arterioles so that the heart is able to pump the blood against a lowered mean peripheral resistance.

These general comments on the types of improvements that may be sought in the field of anesthesia have been made in the hope that they will stimulate the medical profession to accept the new developments as they come along and thereby hasten their transfer from the field of speculation to reality.

MARY FRANCES POE, M.D.

Burstein, C.: Treatment of Acute Arrhythmias during Anesthesia by Intravenous Procaine. *Anesthesiology*, 1946, 7: 113.

In a series of 14 anesthetized patients with acute arrhythmias during intrathoracic operation, single doses of procaine ranging from 30 to 70 mgm. were injected intravenously. No deleterious effect was observed; on the contrary, cardiocirculatory improvement was often effected. Three case reports, 1 with electrocardiographic tracings, are presented.

Cardiac hyperirritability may be expected during the course of surgical intervention upon the heart. Direct stimulation of sensitized cardiac tissue, and other accessory factors are to be considered.

The preponderance of dysrhythmias from pericardial stimulation is probably explained by the fact that the pericardium is richly supplied by a plexus of nerve fibers. Other factors which may contribute to cardiac hyperirritability are the psychic emotional state of the patient, the anesthetic agent, the method employed, and the injection of certain drugs. Endotracheal intubation may cause cardiac disturbances through a vagovagal reflex. This reflex is particularly dominant when the anesthetic agent used is itself cholinergic. Spraying the larynx with 10 per cent cocaine prior to intubation is recommended to obviate such vagotonic effects. The administration of analeptics should be carefully weighed in acute cardiac emergencies. Whatever stimulating properties they may have in the unanesthetized state may be lost during anesthesia, and further, these drugs may increase respiratory and circulatory depression.

The use of procaine during anesthesia to diminish cardiac irritability is based upon experimental findings that procaine applied locally to the heart reduces irritability of the myocardium, and that the

injection of procaine protects against the development of ventricular fibrillation during chloroform anesthesia, and against cardiac arrhythmias during cyclopropane anesthesia produced by epinephrine. It is confirmed that arrhythmias with pacemaker derangements can be reverted to the sinus node by procaine. This report shows that even when ventricular fibrillation has set in during cyclopropane anesthesia, the intracardiac injection of procaine may be followed by a return to sinus rhythm. General anesthesia probably affords specific protection against the stimulating action of procaine on the central nervous system.

In all these cases the procaine solution was injected rapidly into one of the large antecubital veins of the arm. Whether the direct intracardiac injection is to be preferred is as yet undetermined. Further studies are needed to determine the optimal dose.

MARY FRANCES POE, M.D.

Cavalcanti, J.: Hypotension and Spinal Anesthesia. The Veritol Test (Hipotensão e a qui-anestesia. A prova do veritol). *Brasil med*, 1945, 7: 465.

Hypotension represents one of the sequelae of major importance following spinal anesthesia.

Two main factors are responsible for the fall of the blood pressure following spinal anesthesia: (1) blocking of the vasomotor system, with a resulting dilatation of the blood vessels in the somatic as well as visceral area, and (2) paralysis of the intercostal muscles which diminishes the respiratory excursions and interferes with the return of the blood to the heart.

To counteract this hypotension caused by spinal anesthesia the author discontinued the use of epinephrine and cardiazol-epinephrine and replaced these drugs by veritol which gives more satisfactory results. The author also recommends the veritol test, which is performed in the following manner:

After the systolic and diastolic pressures and the frequency of the pulse have been recorded, 1 ampoule of veritol is injected intramuscularly. Three minutes later the blood pressure and frequency of the pulse are again recorded. If the arterial pressure rises and the frequency of the pulse remains unchanged, the test is considered positive and it indicates a good reaction of the vasomotor system. If, however, the arterial pressure following an injection of veritol does not undergo any modification and the pulse frequency rises, the test is considered negative and serves as a contraindication to spinal anesthesia.

JOSEPH K. NARX, M.D.

Cole, F.: A New Lethal Dose of Curare, with Some Observations on the Pathology Produced by Large Doses. *Anesthesiology*, 1946, 7: 190.

In view of the widespread use of curare today in anesthesia and neurology, a study seemed advisable to determine (in the laboratory animal) whether or not very large single doses of this drug could be harmful in the presence of adequate pulmonary

ventilation, what the harmful effects might be, and possibly what a new lethal dose of curare might be when there is no association with a preventable anoxia. Intocostrin was used throughout.

The anoxic lethal dose was found to be 0.065 c.c. (1/15 c.c.) per pound in the dog. On the injection of curare directly into the vein, the anoxic lethal dose was shown to be unaffected by cyclopropane oxygen anesthesia, with which curare is commonly administered in man.

The possibility of a cumulative effect of curare is indicated by the death of a dog following the administration of what appeared later to be a sublethal dose. It is suggested that the use of curare on succeeding days may be associated with a heightened effect of the drug.

An unidentified anticurare effect was encountered with the technique of tracheal intubation, cyclopropane-oxygen anesthesia, pentothal induction, and the administration of curare with saline solutions through rubber tubing. A solution to the phenomenon was not essential for the purpose of these experiments but it might explain variations in the curare effects in man, and might be a clue to an anti-curare mechanism which could be useful in terminating the effect of an overdose of curare. The sudden deaths of 2 dogs after apparent complete recovery suggest that the animals were in a dangerous state on emergence from the deep curarization.

There is a nonanoxic lethal dose of curare. Dogs can make complete recovery, with artificial respira-

tion, after receiving five times the anoxia lethal dose of curare, or 0.33 c.c. of intocostrin, per pound of body weight. Complete recovery was made in 1 case following the administration of 1 c.c. of intocostrin per pound (fifteen times the anoxic lethal dose); artificial respiration was maintained for 18 hours. Prostigmine does not appear to be a perfect neutralizing agent for large doses of curare.

Bronchiole or intercostal spasm is suggested as occurring immediately following the injection of large doses of curare because of the greater amount of force required to raise the chest wall during artificial respiration. A temporary unavoidable cyanosis following the administration of large doses of curare, in the presence of proper artificial respiration, may be due to this respiratory spasm or to a pro-cardiovascular system appears to be affected by large doses of curare. Marked slowing of the pulse rate occurred whenever artificial respiration was stopped.

No clinical evidence of brain damage could be found other than that due to anoxia.

Bloody diarrhea was a constant finding in the later experiments, in which very large doses of curare were used. Postmortem examination in 2 cases revealed the presence of severe mucosal hemorrhages involving the entire intestinal tract. There may be at least a relative contraindication for the use of large doses of curare when there is a disease of the intestinal tract.

MARY FRANCES POH, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Whiteleather, J. E., Semmes, R. E., and Murphey.
F.: The Roentgenographic Signs of Herniation
of the Cervical Intervertebral Disc. *Radiology*,
1946, 46: 213.

The authors describe herniation of the cervical disc as observed roentgenographically in 32 cases verified by operation, and 106 additional cases not verified but presenting the same clinical and x-ray findings.

The two divisions of the spine which undergo the greatest stress are the lower lumbar and lower cervical segments. One might expect to find degenerative disc changes in these regions more commonly than elsewhere, and this is clinically true. The only significant difference is that in the cervical region the spinal canal and intervertebral foramina are smaller than in the lumbar spine; hence, a small herniation is more likely to be symptomatic. In addition, the nerve roots in the cervical region emerge from the dura at right angles and are compressed as they pass through the intervertebral foramina, while in the lumbar region the angle of emergence is acute and the roots are compressed against the vertebra above their exit from the canal.

Lateral herniation of the cervical disc usually follows a relatively slight trauma, although some patients are unaware of any specific injury. Not all displacement of disc tissue results in clinical symptoms. The lesions which produce nerve root compression are of two types:

1. Extruded nodules of nucleus pulposus which are soft and radiolucent but are easily recognized when the posterior ligament is incised. These later undergo ossification and, becoming visible, are often interpreted as arthritic spurs.

2. Protrusions of the disc with neither rupture of the annulus fibrosus nor extrusion of the nucleus pulposus. Ossification occurs in the late stages of this type also.

The first symptom is usually stiffness of the neck with pain radiating to the occiput. This may disappear or recur at intervals if the degree of injury is slight. After a period of days, months, or years, pain may be felt in the shoulder, over the anterior chest wall, the medial border of the scapula, and down the arm, frequently accompanied by sensory changes in one or more fingers. The chest pain may be so severe that the patient believes he has suffered a heart attack. It may be so mild as to stimulate myalgia, neuritis, bursitis, or arthritis of the shoulder. Movement of the neck, coughing, sneezing, and straining may aggravate the symptoms. Supporting the arm or sleeping with it behind the head may relieve them. The patient may complain of numbness and tingling in the thumb or fingers or a feeling as of an electric shock running down the arm.

Weakness of the grip, vasomotor changes, and, in the late stages, muscular atrophy may be observed.

The head may be carried tilted to one side with the neck extended; muscle spasm and limitation of motion may be present. The patient has a tendency to protect himself against sudden jars and against untoward movements. Of considerable diagnostic importance is the elicitation of point tenderness over the affected nerve root by compression or percussion. A positive "neck compression test" is almost pathognomonic.

The lesion is localized by correlation of the clinical and roentgenographic findings. The distribution of pain and sensory changes and the condition of the tendon reflexes are practically specific. The abnormalities observed on the roentgenograms are:

1. Loss of reversal of normal cervical lordosis, either complete or segmental
2. Narrowing of the intervertebral space
3. Calcified particles of the disc (osteophytes) and proliferative spurs projecting into the foramina and from the anterior margins of the bodies
4. Alterations in size and shape of the foramen
5. Decreased mobility
6. Defects in the myelogram

None of these findings is considered pathognomonic, as some may be present without sufficient nerve injury to produce symptoms. However, when they are correlated with the history, symptoms, and neurological findings, they are highly confirmatory.

Myelography is a fairly accurate diagnostic procedure when carefully done and correctly interpreted.

At present, there is some doubt as to whether the diagnosis of herniated cervical disc can be made more accurately by myelography than by clinical means and standard roentgenograms.

There is much yet to be learned about the treatment of ruptured discs in any part of the spine. Excellent results have been obtained, however, in the early or soft lesions by partial hemilaminectomy and removal of the extruded particles.

Conservative treatment, such as traction and physiotherapy, is first given a trial and frequently affords relief. Operative treatment is reserved for those who do not respond to less radical measures.

HARRY FINE, M.D.

Epstein, B. S., and Davidoff, L. M.: The Myelographic Diagnosis of Extramedullary Cervical Spinal Cord Tumors. *Am. J. Roentg.*, 1946, 55: 473.

The authors report the myelographic findings in 5 patients with extramedullary tumors of the cervical spinal cord or nerve roots, in whom the direct roentgenograms remained negative.

In conjunction with these cases, they describe in detail the technique of myelography for visualization.

Fig. 1. Left, Spot roentgenogram of lower cervical canal revealing normal configuration of the pantopaque column. Right, Spot roentgenogram of oil column in upper cervical spinal canal revealing filling defect on the right at the level of the upper three cervical segments. Perineural fibroblastoma found at operation.

tion of the cervical spinal canal. A standard motor driven tilt table is used which is equipped for roentgenoscopy and spot film roentgenography. The authors inject only 3 c.c. of pantopaque oil into the lumbar subarachnoid space whereas others use 6 c.c. of oil, preferring to aspirate it after examination. The patient is placed on his stomach with his head turned to one side. First the table is tilted slightly caudalward so that all the oil gathers in the lumbar sac, then it is tilted slowly in the opposite direction until the head reaches 10 degrees below the horizontal.

During this maneuver the passage of the oil is carefully observed roentgenoscopically. The column usually halts at the level of the first lumbar vertebra. By requesting the patient to strain it will advance another 3 or 4 cm. At this point the patient is asked to assume the knee-chest position gradually and the oil will pass through the thoracic canal. When the upper dorsal region is reached the patient is returned to the prone position and the table is tilted slightly caudalward. The oil is then permitted to collect in the lower cervical canal. From here on the column assumes a transitory "U" configuration splitting into two lateral ribbons of greater density between which the remainder of the oil collects. Persisting filling defects confined to one region in the presence of good visualization of the other pouches

are considered indicative of cervical spinal cord tumors (Fig. 1). Patients with kyphosis or scoliosis of the thoracic spine are examined in the lateral position. Sometimes it is impossible to prevent the passage of the pantopaque oil into the basilar cisterns. A prompt reversal of the tilting will get the oil back into the cervical spinal canal, permitting at the same time the observation of the descent in a manner similar to that following a cisternal instillation.

The 5 cases are presented in detail and their roentgenograms reproduced. The duration of the symptoms varied from 4 months to 2 years. The onset was always insidious. Four of the patients complained of pain in the right shoulder, in 2 there were symptoms referable to the lower extremities, and 1 patient had a complete tetraplegia. The pattern of pain showed no regional characteristics but varied with the results of the pressure produced in each individual.

The most important finding in the cerebrospinal fluid was an increase of the protein content. In 2 cases there was a complete fluid block, in 2 a partial block, and in 1 case there was no block. Three of the tumors were perineural fibroblastomas and 2 were meningiomas. All were extramedullary and could be removed with complete recovery of the patients.

T. LEUCUTA, M.D.

Hodson, C. J.: *The Localization of Foreign Bodies in the Chest. Brit. J. Radiol.*, 1946, 19: 70.

The author's report is based on the method used at an Army Chest Center where 200 cases were observed at operation. It was the belief and policy that all foreign bodies retained within the rib plane or the thoracic cavity, measuring over 1 centimeter in any one direction, should be removed provided the operating risk appeared reasonable. Stress was laid on the importance of close co-operation between the radiologist and the surgeon.

The surgical approaches, determined by the site of missile, pleural pathology, etc., were: (1) lateral thoracotomy, (2) anterior thoracotomy, (3) posterior or parascapular thoracotomy, and (4) local approach.

The localization was by radiography, fluoroscopy, or both. Anatomical localization, rather than skin markings, was emphasized. Tangential fluoroscopy was indicated particularly in the so called "blind" areas (most of the chest wall, the apical, paramedias-tinal, and diaphragmatic regions).

The localization of missiles in the following regions was described in more detail:

1. Peripheral foreign bodies. Needle localization was usually the method of choice. The possibility of the incorporation of the foreign body within callus was stressed.

2. Mediastinal foreign bodies. Localization was usually best done from films. The superior mediastinal localization usually required both films and fluoroscopy; occasionally esophageal identification with barium and tracheal outline with lipiodol were necessary.

3. Posterior mediastinal foreign bodies were marked by vertebral level and their relation to the aorta, trachea, and esophagus.

4. Paradiaphragmatic foreign bodies required aspiration of effusions and, when possible, expansion of the lower lobes before localization. Movement of the diaphragm in relation to the foreign body offered considerable assistance. Induced pneumoperitoneum was of little value.

5. Para- and intracardiac foreign bodies. Fluoroscopy was the method of choice for both large and especially small foreign bodies.

6. Intrapulmonary foreign bodies. Films usually sufficed, although "blind" areas required tangential screening.

R. B. Lewis, M.D.

Benedict, E. B.: *Correlation of Gastroscopic, Roentgenologic, and Pathological Findings in Diseases of the Stomach: An Analysis of 245 Proved Cases. Am. J. Roentg.*, 1946, 55: 251.

In the present analysis of 245 cases of diseases of the stomach, the author emphasizes the importance of co-operation between the roentgenologist, the gastroscopist, and the pathologist. Gastroscopy is supplementary and complementary to roentgenology, but is not a rival method. A group of 245 carefully selected cases was chosen for this study. In each of these there has been a roentgen examination, a gastroscopy, and a pathological report. The

cases included carcinoma (125), gastric ulcer (50), duodenal ulcer (25), jejunal ulcer (8), gastritis (16), benign tumor (7), lymphoma (5), sarcoma (1), metastatic carcinoma (3), and normal stomach (4).

In the 125 cases of carcinoma, the roentgen examination and gastroscopy were equally good 67 times, equally doubtful 3 times, and equally wrong 3 times. In the remaining 52 cases roentgenology proved the better method 32 times, and gastroscopy, 20 times. In 25 of the 32 cases in which the roentgen ray was more valuable, gastroscopy failed to demonstrate the lesion at all. The reasons for the failure were mechanical difficulties such as the inability to see lesions of the lesser curvature of the antrum, pyloric area, and pylorus, especially if they were hidden around the corner behind the angulus, or of the fundus if they were located high up in the blind area toward the lesser curvature, or, finally, if the secretion of the stomach was excessive. In the other 7 cases the causes of failure were manifold. The cases and the results of the examinations are briefly described.

The 20 cases in which gastroscopy appeared more valuable than roentgen examination were grouped as follows: (a) roentgen examination: gastric ulcer? carcinoma; gastroscopy: carcinoma (7 cases); (b) roentgen examination: benign gastric ulcer; gastroscopy: gastric ulcer? carcinoma (5 cases); (c) roentgen examination: doubtful; gastroscopy: carcinoma (1 case); (d) roentgen examination: gastric ulcer; gastroscopy: malignant polyps (1 case); and (e) roentgen examination: gastritis; gastroscopy: carcinoma (1 case). Illustrative cases are cited for each group and briefly presented.

In the 50 cases of proved benign gastric ulcer, both methods were equally correct 16 times and equally doubtful 9 times. In 27 cases the roentgen examination was superior to gastroscopy, and in the remaining 4 cases the opposite was true. As in the cases of carcinoma, the gastroscopic failures were due chiefly to mechanical difficulties. Seven times it was impossible to see the ulcer in the prepyloric region, five times, on the lesser curvature of the antrum; two times, high on the lesser curvature; once, near a gastroenterostomy stoma; once because of excessive excretion; and once because of spasm of the body of the stomach. In the other 4 cases in which roentgen examination was superior to gastroscopy, the ulcers were well seen but could not be accurately identified. Six illustrative cases are described in greater detail.

Duodenal ulcers cannot be seen directly through the gastroscopist but they are included because of the associated gastritis.

In 8 cases of proved jejunal ulcer (following gastroenterostomy) both methods were equally correct 3 times, equally incorrect twice, and in 3 the roentgen ray was superior to gastroscopy.

Since gastritis is the most common disease of the stomach, and since the roentgenologist cannot differentiate between the different types, gastroscopy here is of great importance. Superficial gastritis as seen gastroscopically corresponds to the acute gastritis

described by the pathologist. Elsewhere, the author, in association with Mallory, studied 51 resected specimens and found agreement in two-thirds of the cases of superficial gastritis, two-thirds of the cases of atrophic gastritis, and three-fourths of the cases of hypertrophic gastritis. In a series of 1,300 cases examined gastroscopically, chronic or hypertrophic gastritis without other gastric or duodenal pathology was found in 117 cases (9 per cent). A roentgen diagnosis of gastritis was mentioned in only one-third of the 117 cases. Certain typical types are briefly discussed and illustrated.

In 7 cases of proved benign tumors the two methods seemed about equal on three occasions; twice the roentgen ray was better, and twice gastroscopy was better.

Of the 5 cases of lymphoma, in 3 the lesion seemed quite typical of carcinoma by both methods of examination, in the fourth case the diagnosis was inconclusive, and only in the fifth case was lymphoma mentioned by either method of examination.

In the 2 cases of sarcoma, a correct diagnosis was made on the basis of histopathological study.

This was also true of carcinoma of the pancreas (in 3 cases) which proved at operation to have invaded the wall of the stomach, although the malignant nature of the lesion was suspected in 2.

In the 4 normal stomachs, the roentgen examination and gastroscopy were equally correct.

The general conclusion is that both the roentgen examination and gastroscopy occupy a very important place in the diagnosis of gastric disease. If the gastroscopist can get a satisfactory view of the lesion his chances of reading a correct diagnosis are greater than those of the roentgenologist. Further technical improvement in gastroscopy is desirable.

T. LEUCETIA, M.D.

Gilbertson, E. L., and Kirklin, B. R.: A Review of the Literature on Roentgenology of the Gastrointestinal Tract for the Year 1944. *Gastroenterology*, 1946, 6: 112.

This article is a review of the literature on roentgenology of the gastrointestinal tract for the year 1944.

Templeton and Moore studied 29 patients who had cardiospasm and strictures in the esophagus. Examination was made with the patients in the prone position. They stated that three types of muscular action are seen normally in the esophagus: (1) a primary wave, a part of deglutition, forcing the bolus along as it travels down the esophagus; (2) a secondary wave, not initiated by swallowing, which begins in the region of the aortic arch; and (3) a tertiary or localized contraction, which is nonperistaltic. In cardiospasm the primary wave fades out at the suprasternal notch and the main action resembles the localized or tertiary contractions seen in older patients. Bakwin, Galsen, and LeVine made roentgen studies of the esophagus after a meal of opaque material had been given to 32 normal infants ranging in age from 3 weeks to 22 months. They found that

the normal esophagus in the infant is a distensible tube that may be as wide as, or wider than, the vertebral column. Hansson presented 3 cases of varices of the esophagus in children. He suggested a roentgenogram of the esophagus in all cases of unaccountable gastrointestinal hemorrhages in children. Two cases of peptic ulcer of the lower part of the esophagus, and the advantages of roentgenoscopic and roentgenographic study in these cases were described by Lust and Peskin. Adams related his experiences with 28 surgically explored cases of carcinoma of the esophagus from 1937 to 1943. During this time 100 cases were encountered at the Lahey Clinic. In 72 cases the carcinoma was too far advanced at the time of diagnosis to justify exploration. Only 16 lesions, less than half of those explored, were suitable for resection. A good, brief discussion, including the anatomy and nerve supply, and the theories of pathogenesis and differential roentgenological diagnosis of cardiospasm was given by Niehaus. He reported statistics on 40 cases. A brief discussion of diaphragmatic hernias with special reference to parasternal herniations or herniations through the foramen of Morgagni was presented and illustrated with cases by Ritvo and Peterson. They concluded that the occurrence of a rounded mass in the anterior inferior portion of the right lung adjacent to the right border of the heart requires that parasternal hernia be considered the diagnosis until it is disproved by examination after a barium enema and opaque meal. Thirty-eight cases of diaphragmatic lesions were discovered in routine roentgenograms of the chest of 412,149 patients by Kinzer and Cook. They classified only 3 of these as true diaphragmatic hernias. In the 35 other cases the lesions were congenital evolutions of the diaphragm; 3 of the 35 cases were reported in detail.

Hefke stated that a large number of cases of pyloric stenosis in children can be diagnosed on roentgen examination of the stomach. The opening time of the pylorus is of much more value than the emptying time of the stomach. The most important roentgenological sign is the actual demonstration of the narrowed prepyloric canal. Wakefield stated that hypertrophic pyloric stenosis in adults is probably more common than is usually thought. He was of the opinion that it should be considered in the differential diagnosis of any pyloric obstruction. Most of the patients (more than 80 per cent) who have hypertrophic pyloric stenosis are males. He quoted Kirklin's criteria for the roentgenological diagnosis; namely, mushroom configuration of the base of the duodenum and elongation of the pyloric canal. Templeton gave consideration to the normal and pathological roentgenographic appearance of the stomach after various types of anastomoses. He stated that roentgenological examination of the postoperative stomach is difficult and depends largely on good roentgenoscopic technique and familiarity with the different surgical procedures used in the treatment of ulcer and carcinoma. Warren and Meissner stated that chronic gastritis may be a precursor of carcino-

ma, but not all of its types and stages are necessarily precancerous. They examined tissue from 356 stomachs which were removed because of carcinoma or peptic ulcer. According to the authors the histological changes should be divided into the exudative and epithelial; the former have no significance as a precursor of cancer. When epithelial changes become severe, they are similar to premalignant lesions elsewhere in the body. Ude said that the nature of a pathological lesion may be determined more accurately by a skilled roentgenologist than by a surgeon upon visual inspection or palpation of the gross surgical specimen. A detailed report on the incidence of peptic ulcer in various countries, and the age groups in the two sexes in various occupations and in relation to body build was made by Patterson. According to Blum, only 15 proved cases of benign gastric ulcer on the greater curvature have been reported in the literature. He added another case. Palmer and Humphreys showed the factors involved in the actual or apparent resolution of a carcinomatous ulcer in the stomach, which make it simulate a benign ulcer. This apparent resolution is attributed to peptic digestion of the carcinoma and adjacent tissue. Tumors of the cardia of the stomach are best visualized by demonstrating a tumor mass through gas in the cardia. In some cases there is sufficient gas in the stomach for this. Wasch and Epstein described and illustrated the use of a Levine tube to create a large gas bubble. Methods of examination and the roentgenological findings in carcinoma of the cardiac end of the stomach were considered, and a new roentgenological sign consisting of a cardiac pouch was described. This sign had been demonstrated in 5 cases by Elkeles. From the Presbyterian Hospital in New York, St. John, Swenson, and Harvey related an experiment in the early diagnosis of gastric carcinoma. They made rapid roentgenoscopic examinations on 2,232 patients more than 50 years of age who were in the hospital for reasons other than gastrointestinal complaints. In this group of patients they found 3 unsuspected malignant gastric tumors and the diagnosis was confirmed later at surgical exploration. Marshall and Aronoff reported the types of gastric tumors found in 464 patients operated on at the Lahey Clinic in a 5 year period. Benign tumors constituted 2 per cent of the group; 3.2 per cent were sarcomas; and the remainder, 94.8 per cent, were carcinomas. In a brief but good discussion of the roentgenoscopic signs of tumors of the posterior wall of the stomach, Jonas mentioned diversions of the normal path of the initial inflow of barium into the stomach, the appearance of a white barium free circle on palpation, a central black spot in the white circle denoting ulceration or crater, and abrupt interruption of the mucosal folds. Signs of infiltration include loss of flexibility, absence of peristalsis, and deformity or raggedness of the outline of the stomach.

Retropertitoneal perforations of the duodenum were discussed by Jacobs, Culver, and Koenig. The great majority are due to trauma and occur in the

second or third portion. The value of proper roentgenological examination in making the early diagnosis of this otherwise highly fatal perforation was shown. The roentgen findings in 228 cases of mechanical ileus in which the obstruction was situated within the abdominal cavity were presented by Friman-Dahl. Bartels and Harris emphasized the occasional occurrence of intestinal obstruction with negative roentgenological findings and of positive roentgenological findings in cases in which obstruction is not present. Five cases were reported in which a preoperative diagnosis of obstruction was made and the operative findings failed to reveal obstruction. Maissa discussed and illustrated the roentgenological diagnosis of ileitis with special reference to tuberculous ileitis. A review of 26 primary malignant tumors of the small bowel encountered during a period of 16 years was presented by Warren. In his review the second portion of the duodenum and the duodenojejunal junction were the most frequent sites. Two cases of tumor of the small intestine were reported by Smith, Good, and Gray. In discussing the roentgenological aspects of tumor of the small bowel Good stated that roentgenological examination of the ileum and jejunum should be done in cases in which no lesion in the rest of the alimentary tract has been found to explain the bleeding. During a period of 3 years at the Mayo Clinic, 266 potential sources of bleeding were found in the stomach and duodenum to each 1 found in the remainder of the small intestine.

The clinical features, diagnosis, and treatment of carcinoma at the various anatomic sites in the colon were discussed by Beilin, and the diagnosis and treatment of carcinoma and lymphosarcoma of the colon were outlined by Tilton. Wolfer commented in detail on some of the clinical and roentgenological aspects of polyposis, carcinoma, and diverticulitis of the sigmoid and pelvic portions of the colon. After a study of 24 cases Klein said that lymphogranuloma venereum involving the colon has certain definite roentgenological characteristics. These include destruction of the mucosa, rectal stricture, distention of the rectal pouch, and single and multiple perforations and perisigmoidal sinus and fistulous tracts. The clinical and roentgenological signs of postirradiation stricture of the rectum and sigmoid after treatment for carcinoma of the cervix were well outlined by McIntosh and Hutton. Symptoms seldom are due to recurrent malignancy and should be considered secondary to irradiation until proved otherwise. Anatomic defects may be present without functional impairment. The value of roentgenological examination of the gastrointestinal tract in chronic diarrheas of childhood was expressed by Diamond.

The details of radiographic technique and the principles of roentgenological interpretation of cholecystography were discussed by Sosman. He favored the use of prodiol and stressed the importance of good roentgenograms if an accurate diagnosis is to be made. Huber reviewed the literature regarding the use of cholecystography in jaundiced

patients and found a great divergence of opinion as to its value and safety. He presented cholecystographic findings in 50 cases of jaundice. He concluded that cholecystography in jaundice, while apparently not harmful, is of little value when jaundice is increasing, and can be deferred if jaundice is decreasing. The importance of a plain abdominal roentgenogram in demonstrating stones of the common and cystic ducts was noted by Sahler and Hampton. They stated that stones can be suspected in any case in which calcification is seen in the region of the gall bladder and common duct, whenever there is milk of calcium bile, or whenever the patient is jaundiced. Additional roentgenological studies with opaque media may be necessary before a definite diagnosis can be made. Calthrop reported the oral use of pheniodal suspension in 100 cases of cholecystography and considered it a safe, convenient, economical, and satisfactory means of examining the gall bladder. The use and advantages of priodax in visualization of the gall bladder were reported in a well illustrated article by Dannenberg. The advantages of priodax over preparations previously used also were brought out in other articles by Ochsner, Hefke, Bryan and Pedersen, and Vaughan and Eichwald. Ochsner stated that priodax is reliable, easier to take, produces fewer reactions, leaves little residue in the bowel because it is excreted mainly through the kidneys, and is of such density within the gall bladder that stones will be demonstrated if present. Hefke's reports were based on 600 examinations. Boyden and Rigler noted that previous studies have shown that the gall bladder of women in the last two trimesters of pregnancy empties more slowly than that of nulligravidae women. They found that the rate of emptying of the stomach appeared to have little or no effect on evacuation of the gall bladder and therefore believed that it is not a primary factor in causing the delayed evacuation of the gall bladder in pregnancy. Cholangiography in relation to lithiasis and physiopathology of the biliary tree and some of the difficulties encountered were the subjects considered by Bengolea and his associates.

Poppel and Marshak divided pancreatic lesions into four arbitrary groups in order to study the roentgenological features. In group 1 were lesions of the pancreas which could be seen in the simple roentgenogram; the most usual lesion was calcification. In group 2 were lesions which produced effects on the contiguous structures; of these, carcinoma was the most common. In group 3 were lesions which produced effects on structures not intimately related to the pancreas; for example, peritonitis, as from meconium ileus or acute pancreatitis. In group 4 were lesions which did not produce roentgenological manifestations, such as diabetes mellitus.

The indirect signs of amebic hepatitis in 10 cases were discussed by Munk. Among the signs are elevation of the right side of the diaphragm, restricted or abnormal movement of the diaphragm, secondary pulmonary changes including atelectasis of the right lower lobe, and pleurisy. Thorotrast hepatosple-

graphy was developed in 1929 and consists of roentgen examination of the spleen and liver after the intravenous administration of a stabilized colloidal solution of thorium dioxide. Yater has used this method in several hundreds of cases for 13 years and a follow-up study of 286 patients revealed no harmful effects. Thorotrast is most valuable in the diagnosis of hepatic abscess, but is also of value in the diagnosis of tumors of the liver. The technique of its use and case histories were given by Yater. The colloidal preparation of thorium dioxide, known as thorotrast, was used by McClure and his associates for the demonstration of gross anatomic changes in the liver and spleen. Thorotrast, which is given intravenously, is taken up by the reticulo-endothelial cells, and thus a clearly defined shadow visible by means of the roentgen rays is produced. The authors maintained that no ill effects have been proved to result from the thorium. They first administered it 10 years ago and no untoward symptoms have developed.

The diversity of opinions concerning the value of roentgenology in the diagnosis of appendicitis was reviewed by Gomez. He expressed the belief that roentgen examination is important not only because it rules out or confirms disease in other organs of the gastrointestinal tract, but also because it reveals direct and reflex signs in the appendicular region which can be ascertained by the examination. The value of pneumoperitoneum as a diagnostic procedure was discussed by Maxfield and McIlwain. Reiley expressed the opinion that duodenal regurgitation is most often found in association with, or as a reflex from, disease of the upper part of the renal tract. A plea for closer co-operation between the clinician and roentgenologist was sounded by Lehman. He stated that functional derangements in the gastrointestinal tract cannot and should not be diagnosed by the roentgenologist. Roentgenological diagnosis should be limited to organic conditions.

CHARLES BARON, M.D.

Jansson, G.: Roentgenological Skeletal Changes in Myeloma in Childhood. *Acta radiol., Stockh.*, 1946, 27: 73.

Multiple myeloma is usually considered a disease occurring in older people. The author has been able to find only 8 reported cases in children. To this group he adds the following case.

The patient, a boy 9 years of age, was first seen in the spring of 1942, at which time he complained of pain in the back. Associated with this was recurrent fever, progressive anemia, and an increase in the blood sedimentation rate. He was treated in a war hospital from September to December. During this time, because of large numbers of granular casts, leucocytes, and solitary red cells in the urine, a tentative diagnosis of nephritis was considered. By the middle of December, however, the urine was free of albumin, casts, leucocytes, and red cells. On January 1, 1943 the hemoglobin was 22 per cent, the red blood count was 1,370,000, the white blood count

4,300, with 20 per cent neutrophils, 75 per cent lymphocytes, and 3.5 per cent myelocytes. In spite of repeated blood transfusions the anemia progressed and the patient expired on February 14, 1943.

Roentgen examination of the skeletal system revealed extensive changes. The pelvic bones and the upper ends of both femurs showed multiple, large and small, cystlike, punched out areas of destruction. There were similar areas in the distal ends of the femurs and proximal ends of both tibiae. The epiphyses were also involved, as well as the proximal ends of both humeri and scapulae. There was marked osteoporosis with collapse of all the vertebral bodies. Some of the bodies were represented by thin plates, others had a biconcave configuration. The intervertebral plates were larger than normal. There were no cystlike areas within the vertebral bodies. The skull and ribs were normal in appearance.

The roentgen diagnosis was Schüller-Christian disease, although exophthalmos and diabetes insipidus were not present. Because of the patient's age, metastatic carcinoma was thought to be unlikely. The correct diagnosis was made from the findings at autopsy. The myelomatous process had infiltrated the liver, spleen, and kidneys, and had diffusely involved the vertebral bodies, causing their collapse.

Garland, L. H., and Thomas, S. F.: Spondylolistheses; Criteria for More Accurate Diagnosis of True Anterior Slip of the Involved Vertebral Segment. *Am. J. Roentg.*, 1946, 55: 275.

Spondylolisthesis has of late acquired increasing importance in connection with the care and disposition of military and industrial personnel claiming disability. The diagnosis of advanced cases is simple, but in the early stages various confusing factors may arise.

The term spondylolisthesis means an anterior displacement of a vertebral body with solution of continuity of its posterior arch (spondylos, a vertebra; olisthesis, to slip). The solution, which nearly always is bilateral, consists of slender fissures in the interarticular portions of the neural arch. It can occur in any segment of the spine, but is most common in the fifth lumbar vertebra. Other confusing types of displacement are: (a) anterior dislocation of a lower lumbar vertebra usually associated with fractures of the articular processes either on a traumatic or pathological basis; (b) elongation of a lower lumbar body (localized platyspondyly), which may be congenital or acquired, and (c) foreshortening of a lower lumbar body (localized brachyspondyly), which may or may not be associated with interarticular defects in the neural arch. If defects are present a spondylolisthesis, Grade I, may erroneously be diagnosed.

One often sees two additional terms used rather loosely: prespondylolisthesis, which is applied to a condition in which there are interarticular defects in the neural arch of a vertebra, but without forward displacement of the body of the vertebra, and reverse

spondylolisthesis, a term which is used for the designation of a situation when the vertebral body lies or appears to lie on a plane dorsal to that of its fellows. Both of these terms must be condemned.

The cause of the defect in the neural arch is unknown. A congenital origin was advanced but anatomists cast some doubt on this. A traumatic etiology either at birth or in infancy, with vascular disturbances of the neural arch, is more probable. The normal stress of the weight of the body, combined with such varying factors as occupational strain, weakening of the muscles and ligaments from age or disease, and softening of some of these structures from pregnancy, then causes in time the forward slipping of the involved vertebral segment.

From the pathological standpoint, true spondylolisthesis is classified as minimal, early, moderate, and advanced. The vast majority of the cases observed by the authors were in the minimal stage. In this stage the posterior one-third of the vertebral segment is retained in more or less normal alignment, and the anterior two-thirds show a forward displacement of 1 or 2 mm. which sometimes increases in the erect position or with heavy weight bearing. There may be associated anomalies, as, for example, cleft in the spinous process, aplastic articular process or processes, etc. In the early and moderate stages the changes are correspondingly more pronounced. In the advanced stage the forward displacement is marked and sometimes associated with downward tilting of the involved vertebral segment. The slipped body may even overlap the mid-sacrum. In addition, there are variable degrees of thinning of the subjacent disc, much new bone formation on the fifth lumbar and first sacral bodies, gross distortion of the neighboring ligaments and soft tissues, and stretching or compression of the segmental spinal nerves.

The diagnosis in the minimal and early stages is a roentgenological problem. It requires the demonstration of (a) unequivocal forward displacement of a vertebral body, in the presence of (b) a defect, or defects, in the neural arch. Correct positioning and the examination in several standardized views is essential. The following criteria may be of additional value: (c) overlapping of the shadows of the transverse process of the involved segment on those of the subjacent one, (d) obscuration of the margins of the involved body, and (e) apparently increased density of the fifth lumbar body, owing to overlapping.

The authors discuss in detail the various roentgen criteria which aid in the recognition of an anterior and posterior margin displacement.

Altogether, they studied roentgenograms of the lumbosacral spine in 170 consecutive cases, and determined the length, shape, and relative position of the body of the fifth lumbar vertebra. The results are tabularly presented, and typical roentgenograms are used for the purpose of illustration. Briefly, it was found that 25 persons (14.7 per cent) had more or less foreshortened last lumbar segments. In 15

of these no defects of the neural arch were present, but the posterior edge of the last lumbar body lay from 1 to 3 mm. ventral to the plane of that of the first sacral segment. In the other 9, arch defects were present, but in only 4 was the anterior margin of the fifth lumbar body ventral to the test line, representing true spondylolisthesis. There were 4 additional cases of true slip with bodies of normal shape and length.

Widmann, B. P.: Results of Roentgen Treatment of Leucemia. *Am. J. Roentg.*, 1946, 55: 377.

Roentgen therapy in chronic leucemia is an excellent palliative measure. The author reports the course and the results of treatment of 110 patients. Of these, 46 were too ill to be treated. A follow-up was not available on 15 patients who were treated with irradiation. A follow-up of the remaining 49 patients revealed that 21 were still alive; 12 patients lived 6 months or less; 17 lived 3 years or more; 7 lived more than 5 years; 4 lived 13 years; 3 lived 18 years; 1 lived 19 years.

The main symptoms were weakness, loss of weight, cough, dyspnea, edema of the extremities, abdominal pain, splenic and generalized lymph node enlargement. Biopsies were taken in 21 per cent of the cases. There was practically no difference in the course between the lymphoid and myeloid leucemia.

The average duration of life from the time of treatment was 3.3 years in the lymphoid group and 2.7 years in the myeloid group. It is possible that the long life of a few of the patients was due to the benign character of the disease and not to irradiation. The blood count is a good criterion of the progress of the disease. Treatment was given only when the symptomatology warranted therapy. Some patients have a tolerance for a high white count. The basal metabolic rate is a pre-indicator of the blood picture. An increased basal metabolic rate indicates an early rise in the white blood count; it is not necessarily an indicator of the clinical condition of the patient.

Technical factors used in the treatment of patients were variable, ranging from 125 to 200 kilovolts. The spleen, mediastinum, ribs, and enlarged lymph nodes were treated. The long bones were treated only when whole body irradiation was given. Although the life span in this series of patients may have been only slightly increased, the author is of the opinion that irradiation is an excellent palliative procedure. In more than 50 per cent of the cases treated, the patients were restored to normal efficiency.

Maurice D. Sacas, M.D.

Den Hoed, D.: Carcinoma of the Larynx after Roentgen Irradiation (Kehlkopfkrebs nach Strahlenebehandlung). *Acta radiol.*, Stockholm, 1946, 27: 20.

The author calls attention to 2 cases of carcinoma of the larynx following x-ray irradiation of the neck, which had been reported by Losser, and adds 2 cases of his own.

The first patient was a man who had been irradiated in 1915 at the age of 16 for tuberculous lymph-

omas. He had probably received about 20,000 r. to the right side of his neck. In 1939, at the age of 40, an ulceration which did not respond to treatment with ointments was seen in the treated skin area. In 1942 a nodular ulcerating tumor involving the left half of the larynx was observed together with metastasis in the left neck region. After tracheotomy 6,400 r./air were given to the left neck region in fractionated doses and a single dose of 1,000 r. was delivered to the laryngeal tumor by means of a contact tube through a special tubular guide which was applied under general anesthesia. Complete healing took place. The roentgen ulcer on the other side of the neck improved, although it must have received additional radiation from these procedures.

The second case was that of a 41 year old woman who had received x-ray treatments to both sides of her neck for tuberculous glands 25 years before her visit to the author in 1940. Among other typical irradiation changes, the skin showed an ulceration under the left ear, which was found to be a basal cell carcinoma. It was removed and the defect closed with a skin graft. In 1945 a tumor involving the right arytenoid cartilage and the right aryepiglottic fold was seen and found to be a cornified squamous cell carcinoma. Contact tube treatments were given to the larynx under local anesthesia (22,500 r. in fractionated doses within 4 weeks). Complete healing occurred. The patient was symptom free at the time of the report in 1945.

The author suspects a causal connection between the irradiation treatments to the neck and the appearance of the laryngeal tumor in both cases.

GERHART S. SCHWARTZ, M.D.

Pfahler, G.E.: The Treatment of Hemangioma. *Radiology*, 1945, 46: 159.

Following his experience with 520 cases of hemangioma, the author selected 12 quite different ones, several of them spectacular, to demonstrate the various methods applicable to the treatment of this tumor, and to illustrate the point that the treatment chosen should vary with the point that the treatment details of the treatment, and the age of the patient. Details of the treatment of each case are given. The article is accompanied by photographs of the lesion before, during, and after completion of treatment. The author has found no satisfactory treatment for the port wine type of hemangioma; both roentgen rays and radium have produced atrophy and telangiectasis, and electrodesiccation has given scarring. He believes it best to cover such lesions with a cosmetic. The cavernous and strawberry types, however, have responded satisfactorily in nearly all instances to irradiation, and although experience gamma irradiation has given the most uniformly good cosmetic result, especially when the lesions are relatively superficial, i.e., not over centimeters in depth.

He usually arranges 10 mgm. radium tubes, having 1 mm. platinum filtration, evenly in a plaque the precise size and configuration of the lesion so that it surely reaches the edges thereof, and places it only a short distance (often only 2 mm.) from the surface, timing the exposure so as to give an estimated erythema dose at each application. The duration of the application varies of course with the strength of the plaque, the filtration, and the distance. The distance of the radium from the surface should equal approximately the depth of the lesion. The interval between radium treatments is usually from 6 weeks to 3 months, oftener the latter, for it takes at least this long to obtain the major effect of the treatment.

The fact that radium can be applied without pain and retained by adhesive plaster without immobilizing the patient has made it especially desirable in children. Further, since hemangiomas of the cavernous and strawberry types are relatively superficial, radium has permitted rather sharp limitation of the treatment to the lesion.

The author warns of the necessity for walling off the radium applicator from adjacent normal tissues, especially the eyeball, eyelashes, and eyebrows, tooth buds, and epiphyses.

In the deeper variety of hemangioma, after preliminary surface irradiation, and when there remains

a thick fibrous mass, 10 mgm. radium needles are inserted 1 centimeter apart, and left in place 2 hours. In especially deep hemangiomas, and occasionally in large irregular, more superficial ones (to even the dose), x-ray treatment is added.

The author does not use radium for lesions overlying the testicles or ovaries, and recommends electrodesiccation under local anesthesia instead. The latter method has proved useful for small superficial lesions so located that a slight scar was not objectionable, such as small scalp hemangiomas, but is to be avoided in eyelid lesions because of the danger of contracture. Since radium treatments require a number of visits, and a period of one year or more to accomplish satisfactory results, he recommends electrosurgery with wound suture in cases in which the lesion is large, time is important, and a scar is unimportant, provided the lesion is supported by a good layer of cutaneous tissue and is sufficiently movable to allow suturing. The method is particularly desirable for lesions located over one of the larger epiphyses, where irradiation might cause damage. For lesions over the epiphyses of fingers and toes, however, the author has continued to use radium, for lack of a better alternative, and has as yet encountered no evidence of damage to underlying bone.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Milam, D. F.: Plasma Protein Levels in Normal Individuals. *J. Lab. Clin. Med.*, 1946, 31: 285.

Blood protein determinations were performed on the oxalated plasma of 1,561 presumably normal persons by the semi-micro-Kjeldahl method.

The mean total protein level for white persons was 7.19 gm. per cent, and for colored persons 7.44 gm. per cent. The mean albumin was higher among white than among colored individuals—4.65 and 4.45 gm. per cent, respectively. The globulin level was, therefore, higher in the colored group—3.04 and 2.59 gm. per cent. The mean albumin-globulin ratio was 1.80 among white persons, and 1.46 among colored persons. The difference between the races in globulin levels was twice as great as that between the age and sex groups of the same race. SAMUEL KAHN, M.D.

Hegsted, D. M., Tsongas, A. G., Abbott, D. B., and Stare, F. J.: Protein Requirements of Adults. *J. Lab. Clin. Med.*, 1946, 31: 261.

Nitrogen balance studies were made on 26 adults in apparent good health, with a low protein diet devoid of animal protein. Approximately 50 per cent of the protein used was supplied by white bread, 12 per cent by other cereals, 30 per cent by vegetables, and 8 per cent by fruit. Caloric equilibrium was maintained with sugars, starch and fat.

It was found that the nitrogen requirement is more closely related to the surface area (basal caloric expenditure) than to the body weight. The requirement for maintaining the nitrogen balance was approximately 2.9 gm. of nitrogen (18 gm. conventional protein) per square meter of body surface. A man weighing 70 kgs. would thus require between 30 and 40 gm. of protein, according to his height.

On the same diet, with one-third of the protein replaced by meat, the requirement appears to be 2.4 gm. of protein per square meter of body surface (15 gm. conventional protein). Protein requirement is thus about 17 per cent less on this diet than on the all vegetable diet.

Data on digestibility and biological value were determined. The importance of these two measurements for evaluating the nutritional value of a protein is emphasized. High quality proteins are more efficient, but less efficient proteins may serve equally well, provided that enough can be fed to cover the requirements, with consideration of the specific digestibility and the biological value. The biological value of the low protein all vegetable diet used in the studies was increased from 72.5 to 80.4 by replacing one-third of the protein with meat. The digestibility of the two diets was the same.

There was no measurable objective change in the physical condition of any of the individuals through-

out these studies. Some complained of undue postprandial hunger and fatigue on the low protein all vegetable diet; these complaints were not present on high protein diets.

There was no significant change in hemoglobin, hematocrit, or plasma volume. The total protein, plasma albumin, and plasma globulin tended to decrease on the all vegetable diet, when fed at a level low enough to produce a negative nitrogen balance. The replacement of one-third of the protein in this diet with meat resulted in a prompt increase in the globulin fraction.

It is most unlikely that protein deficiency will develop in healthy adults on a diet in which cereals and vegetables supply adequate calories.

SAMUEL KAHN, M.D.

Madden, S. C., and Whipple, G. H.: Amino Acids in the Production of Plasma Protein and Nitrogen Balance. *Am. J. M. Sc.*, 1946, 211: 149.

The use of whole blood, blood plasma, and plasma substitutes is important in emergencies, battle injuries, burns, chronic infections, and protein depletion due to starvation or disease. It has been shown that the body can make plasma proteins and maintain nitrogen balance when the sole source of nitrogen is a protein digest or a mixture of the 20 essential amino acids. We, as yet, know little very about the influence of single amino acids upon the body metabolism, and recent work with methionine and cystine is just beginning.

Studies on the utilization of amino acids given by oral and parenteral routes in dogs and human beings make it appear that the oral route results in superior utilization for plasma protein formation and for nitrogen balance. Mixtures of synthetic amino acids exhibit a surprisingly good utilization, and no toxicity was found in the doses and concentrations used. Intolerance at times manifests itself by nausea and vomiting, but no evidence of serious or persistent injury has ever been observed in animals or man with the material studied. Glutamic acid and aspartic acid may lower the tolerance of amino acid solutions, but glycine seems to improve such tolerance. Subcutaneous injection of solutions of crystalline amino acids in more than 10 per cent concentrations are well tolerated. Mixtures of the 10 essential amino acids plus glycine given parenterally and yielding less than 800 calories per day did not result in nitrogen balance; only if the caloric value exceeded 1,200 was a nitrogen balance obtained.

Synthetic amino acids are preferable to protein digests because they can be mixed in different concentrations with the aim of combining them for specific purposes; for example, in order to enhance the production of gamma-globulin, a mixture of amino acids contained in gamma-globulin might be used.

Amino acid mixtures are better tolerated than protein digests on parenteral administration, and are more palatable orally, but the use of the former is limited by the need of a large scale production of pure amino acids. A mixture of the so-called 10 essential amino acids in suitable amounts can produce a nitrogen balance if given by mouth, by vein, subcutaneously, or intraperitoneally. The 10 essential amino acids are: threonine, valine, leucine, isoleucine, lysine, tryptophane, phenylalanine, methionine, histidine, and arginine; glycine is usually added. These amino acids are well tolerated by patients suffering from chronic infection, gastrointestinal disturbance, partial obstruction, or cancer cachexia.

ARTHUR J. LESSER, or CANCER

Adcock, J. D., and Hettig, R. A.: Absorption, Distribution, and Excretion of Streptomycin. *Arch. Int. M.*, 1946, 77: 179.

Data are presented regarding the absorption, distribution, and excretion of streptomycin administered by various routes.

Streptomycin was not absorbed to any appreciable extent when given orally or by inhalation. Following parenteral administration it was possible to demonstrate the material in the serum in amounts roughly proportional to the dose. Streptomycin appeared in significant concentrations in the spinal fluid of 3 subjects with meningitis and in the pleural fluid of 2 subjects with pleural effusions. In 2 subjects streptomycin was demonstrated in the bile.

A study on the distribution of streptomycin in various organs obtained postmortem showed that it was present in the kidney in high concentration. Smaller amounts were found in the lung and in the heart muscle, while both the brain and the liver contained virtually none.

From 41 to 86 per cent (mean 65 per cent) of the dose was excreted in the urine within 12 hours of the parenteral administrations of streptomycin. Plasma clearance values ranged from 38 to 67 c.c. of plasma cleared of streptomycin per minute.

WALTER H. NADLER, M.D.

De Lorimier, A. A., Mincar, W. L., and Boyd, H. B.: Reflex Hyperemic Deossifications Regional to the Joints of the Extremities. *Radiology*, 1946, 46: 227.

There are four types of decalcification due to intravascular hyperemia:

1. A discreet mottling, especially found in the tarsal and in the carpal bones.
2. Deossifications in the ends of the bones. The rarefactions were made distinct by the appearance of metaphyseal bands.
3. Deossifications beneath the subchondral cortices. This pattern was found in the peripheries of the tarsal and carpal bones.
4. A combination of two or all three of the previously mentioned phases.

The author reviewed 239 cases. All of the cases of trauma, infection, and neoplasm showed one of

the patterns of deossification mentioned. No relation could be established between the etiology and the pattern of deossification. Deossifications due to disuse and generalized deossification due to nutritional deficiencies or endocrine changes were not reviewed in this series. The theory is advanced that the pattern of deossification is related to the vascular supply of the bone and its anastomoses rather than to the cause of the deossification.

GEORGE I. REISS, M.D.

Keresztesy, J. G., Laszlo, D., and Leuchtenberger, C.: Neutralization of the Inhibition of Tumor Growth. *Cancer Res.*, 1946, 6: 128.

The antagonism between the compounds promoting and inhibiting growth has received increasing attention in the past few years.

Investigation by a method involving the growth of transplanted tumors in mice has shown that various substances, such as inositol, lactobacilli casei factor, and xanthopterin, are effective in inhibiting the growth of tumors. However, among the substances and extracts tested, none was found that stimulated tumor growth. It therefore appears that the transplants were probably growing at a normal rate. A method was then devised to demonstrate the possible growth-stimulating properties of various substances by measuring their interference with inhibitors of tumor growth. This was accomplished by repressing the growth rate of a transplant by injecting mice intravenously with a suitable dose of a proved inhibitor and, at the same time, with a suitable dose of the substance or extract to be tested for antagonistic activity, the amount of inhibitor neutralized being a measure of the degree of interference.

By adopting this method the authors were able to demonstrate that the action of inhibitors can be effectively neutralized by both structurally related and unrelated substances.

Neutralization by approximately equal amounts of inhibitor and antagonist was observed with regard to the inositol and p-amino-benzoic acid, inositol and pyridoxine, and d-desthiobiotin and d-biotin experiments. Thiamin, niacinamide, o- and m-aminobenzoic acid, and leucopterin were slightly active, if at all, in counteracting the inhibition caused by inositol. Interference could be detected when larger doses of some of these substances were given.

While both d-desthiobiotin and an avidin concentrate were effective inhibitors of tumor growth, neutralization occurred when these two materials were tested for antagonism. Impurities in the avidin concentrate may be responsible for this interference.

Although in the studies reported here definite interference has been shown to occur between the inhibitors of tumor growth and their antagonists, chemically related or unrelated, it is impossible at this time to state whether these results have any bearing on the chemotherapy of malignant tumors.

Further investigations with various rapidly growing tissues, malignant and nonmalignant, should be carried out. As the substances tested to demonstrate this phenomenon of interference or neutralization were physiologically active, further studies by the authors are under way with simpler or nonphysiological compounds.

JOSEPH K. NARAT, M.D.

Elsen, M. J.: Betel Chewing among Natives of the Southwest Pacific Islands. Lack of Carcinogenic Action. *Cancer Res.*, 1946, 6: 139.

In general discussions on the relationship of natural compounds or agents to the development of neoplasia, it is frequently suggested that betel chewing is a factor in the etiology of oral cancers throughout those portions of the world where betel mixtures are in use, and to some the habit would assume an importance comparable with roentgen or solar radiation, or tar, in the production of tumors of the skin. However, a specific incriminating factor or substance in the materials employed by betel chewers has not been described, neither is there unanimity of opinion regarding the activity of the betel mixture.

According to the experience of the author and Australian workers, betel chewing in the natives of New Guinea, New Britain, New Ireland, and the adjacent smaller islands does not appear to elicit cancer of the mouth. JOSEPH K. NARAT, M.D.

Morgan, L. O.: Histological Changes in the Central Vegetative Centers of the Hypothalamus in Carcinoma as an Indication of Vegetative Functional Disturbances. *Cancer Res.*, 1946, 6: 142.

The anterior hypothalamus exerts its influence chiefly upon the parasympathetic nervous system and the islands of Langerhans and the posterior hypothalamus chiefly on the sympathetic nervous system and the thyroid and suprarenal glands, while the hypophysis is under the influence of both regions. It is apparent, then, that the hypothalamus utilizes to a large extent the autonomic and endocrine systems in achieving its broad purpose of co-ordinating the vegetative functions in the interest of the total organism.

Thus it seems likely that the nuclei of the hypothalamus, and, perhaps, other closely associated centers outside the anatomical limits of the hypothalamus, are normally in a state of physiological balance. If this be true, then disease, injury, or dysfunction involving one or more of the nuclei would probably tend to throw the entire mechanism out of balance, so that the effects would be more far reaching than might be expected were the nuclei concerned with a single specific function.

It is obvious that hypothalamic dysfunction will exist whenever disease or injury attacks the region directly. It is also possible that disease, injury, or dysfunction in any part of the body, that tends to throw vegetative functions out of balance or to

threaten the welfare of the total organism, may eventually involve the hypothalamus because the central mechanism will be called upon to attempt a restoration of normal function.

Because of these possibilities the striking histological abnormalities that occur in the hypothalamus of the cancer patient may be of considerable significance. Therefore a histological study of 5 nuclei of the hypothalamus in 19 patients with proved carcinoma was made by the author.

Extensive chromatolysis and cell destruction indicated that all these cell groups were involved by carcinoma. The pattern of these changes showed a wide range of variation. A congenital overdevelopment of some of the nuclei was indicated, but the cell destruction that occurs in carcinoma made it impossible to evaluate this factor properly.

The cell changes in the hypothalamus suggest a widespread but variable instability or irregularity of the vegetative functions in the patient with carcinoma. This is in keeping with the findings of numerous investigators who have made functional studies in animals or in human patients with cancer.

GENERAL BACTERIAL, PROTOZOAN, AND PARASITIC INFECTIONS

Friedman, L. L., and Signorelli, J. J.: Blastomycosis; A Brief Review of the Literature and a Report of a Case Involving the Meninges. *Ann. Int. M.*, 1946, 24: 385.

Although blastomycosis, known by 19 different names, is a rather uncommon disease, it is, nevertheless, a very important clinical entity when it does occur because the systemic variety usually terminates fatally. Both systemic and cutaneous forms of the infection can successfully mimic many other diseases frequently encountered. In the skin it is characterized by single or multiple pyogenic granulomatous verrucoid lesions, and in the internal organs by single or multiple granulomatous lesions. Although the failure to appreciate the systemic nature of this disease has been largely overcome, knowledge and real understanding of the clinical entity are still very meager and await further clinical and laboratory research.

The largest number of cases are reported as occurring in Illinois and Louisiana, but cases are also reported in Canada, Australia, England, and South American countries. Agricultural workers, common laborers, and people who live or work in damp unhygienic and wooded places contract the disease. Males are affected eight times more often than females. Any age group or race may be affected. The disease is reported most frequently in the third, fourth, and fifth decades. Infection seems to occur through traumatized skin or pre-existing lesions, but may enter by way of the respiratory tract.

The fungus grows on artificial media, producing budding organisms and mycelia without lateral conidia. In a 20 per cent hydroxide solution prepa-

ration it is identified as a doubly refractile ovoid or round body with granular cytoplasm, from 7 to 20 μ in size. It can often be isolated from purulent drainage, blood, urine, sputum, or stools. Despite dermatological lesions, the fungus must be identified to establish a diagnosis. Complement fixation is not always specific or reliable. It is estimated that from 40 to 50 per cent of all cases of blastomycosis have systemic involvement. The tissues most frequently involved are the unprotected areas of the skin, the subcutaneous tissues, the lungs, and the bones and joints, but any organ may be involved.

Many diseases must be considered in the differential diagnosis: other mycoses, i.e., actinomycosis, coccidioidomycosis, chromoblastomycosis, tinea barbae; pneumonias, tuberculosis, tularemia, syphilis, anthrax, bromoderma, bacterial osteomyelitis, and epidermal carcinomas.

The prognosis of the cutaneous type of blastomycosis is good, as far as life expectancy is concerned, but the disease is generally resistant to treatment. No consistently effective and dependable therapeutic measures are known.

The case report is concerned with a 42 year old colored male laborer, admitted in a comatose condition which was diagnosed as rapid syphilis. The illness began 2½ months prior to admission and progressed rapidly from a nondescript prodrome to purulent cutaneous facial lesions, and systemic involvement of the lungs and meninges. A biopsy of the facial lesion was diagnostic. Death occurred 6 days following admission. JAY P. BARTLETT, M.D.

DUCTLESS GLANDS

Fell, M. L., and Dorfman, R. I.: The Influence of Urinary Cortinlike Material on the Sodium and Potassium Metabolism. *Endocrinology*, 1945, 37: 437.

It has been demonstrated that urinary extract contains material with biological activities similar to those of the steroid hormones of the adrenal cortex. The known effects on adrenalectomized rats are:

1. Increased resistance to low environmental temperatures
2. Maintenance of life
3. Increase of liver glycogen deposition in the fasting animal
4. Prolongation of average work performed by the gastrocnemius muscle
5. Prevention of water intoxication.

The present report is concerned with the influence of urinary cortinlike material on the sodium and potassium metabolism of normal and of adrenalectomized rats.

The studies indicate that the alkaline insoluble urinary extract of normal man caused an increase, rather than a decrease, of sodium excretion in normal rats. Similar results were obtained with the adrenocortical extracts, but desoxycorticosterone acetate caused a significant retention of sodium.

Urinary extracts of normal man (both alkaline insoluble, and soluble ketonic fractions) protected adrenalectomized rats against intoxication, which was similar to the effects exhibited by adrenocortical extracts and desoxycorticosterone.

ARTHUR J. LESSER, M.D.

Reiss, M. J. E. F., and Golla, V. M. L.: The Peripheral Inhibitory Influence of Large Doses of Testosterone on Epiphyseal Cartilage Growth. *Endocrinology*, 1946, 38: 65.

The present investigation was suggested by the clinical experiences with hormonal therapy of acromegaly carried out in the last 5 years, and reported by Hutton and Reiss in 1942.

Several results of this treatment could not be explained, notably the very quick reaction which several patients exhibited after the onset of treatment with estrone and testosterone. Particularly noticeable in this connection was a patient who developed acute acromegaly after male climacteric changes had begun. His predominant pathological symptoms were—apart from the usual acromegalic symptoms—a very marked growth of the costal cartilages (the patient could not close his coat), and the growth of the thyroid cartilage, which caused almost complete aphonia. After the daily injections of 50 mg. testosterone propionate for 10 days, the patient's speech was almost completely normal, and the cartilaginous overgrowth of the ribs not only stopped but regressed sufficiently to enable the patient to unbutton his coat. Such rapid regression could not possibly be explained by the inhibition of the increased production of growth hormone in the pituitary gland only.

In an attempt to solve this problem, hypophysectomized animals were used, with a view to determining whether the growth response to the injection of growth hormone could be influenced by sex hormones.

Some light may be thrown on the growth-hormone correlation by consideration of the effect of certain endocrinological disturbances on body growth, such as the eunuchoidal gigantism after prepubertal castration; the cessation of linear bone growth after sexual maturity is reached, when considerable amounts of sex hormones are circulating in the body fluids; and the increased linear growth during puberty, when only small amounts of sex hormones start to enter the body fluids. Other relevant facts are the growth of cartilage that may occur after the climacteric, sometimes even producing acromegalic changes, together with the observation that the growth of male dwarfs can be increased considerably by small doses of testosterone.

The influence of sex hormones on the pituitary gland has been shown in many experiments. The present investigation, however, supports the view that the sex hormones may also directly influence the growth of the bone in the periphery. The experiments described prove an inhibitory action of large doses on the bone growth. A stimulating action, in

sense, as claimed by Simpson *et al.* in 1944 for comparatively small doses, cannot be excluded.

The daily injection of 4 mgm. of testosterone propionate inhibits considerably the cartilaginous growth produced by the growth hormone on hypophysectomized rats. The results suggest an inhibition of the peripheral growth by large doses of sex hormone. The bearing of these results on explanations of certain physiologic and pathophysiologic growth phenomena is discussed.

Dorfman, R. I., Shipley, R. A., Schiller, S., and Horwitz, B. N.: Studies on the "Cold Test" As a Method for the Assay of Adrenocortical Steroids. *Endocrinology*, 1946, 38: 165.

The adrenalectomized mouse will respond to cortical extract and to desoxycorticosterone acetate when exposed to low environmental temperatures. From rather brief experiments it appears, however, that the mouse is not well adapted for assay purposes. The rat appears to be a more suitable animal in the cold test for the bioassay of urinary cortin. The cold test is simple, rapid, and potentially very sensitive. Its usefulness is marred by an erratic variation in sensitivity of animals from group to group. The cause of this behavior has not been determined. Rough estimates of urinary cortin may be made if one dose of standard is run simultaneously with several unknowns administered at two or more different dose levels. The accurate assay of urinary cortin by the method requires large numbers of animals and quantities of pure hormone which make it impractical for extended routine use. Sufficient data were obtained to show that a pooled sample of normal male urine contained the equivalent of 0.6 mgm. of 11-dehydrocorticosterone per liter.

Houssay, B. A.: The Effects of Suprarenal Insufficiency on Pregnancy and the Offspring (*Acción de la insuficiencia suprarenal durante la preñez, sobre la madre y el hijo*). *Rev. As. med. argent.*, 1946, 60: 83.

Experiments were conducted by the author with the main purpose of determining the effect of suprarenalectomy of the adult rat on the suprarenal glands of the fetus. Also other observations were made.

When pregnancy was present both suprarenal glands were removed. Some of the rats received no salt whatsoever, while others were fed 1 per cent sodium chloride solution *ad libitum* in addition to a stated diet.

Forty-four rats were observed and divided into a number of groups for different types of studies. The white rats used always possessed microscopic accessory glands which were not visible to the naked eye but became quite large after suprarenalectomy.

During the first period following the operation there was glandular insufficiency, although generally it was not fatal—the symptoms became attenuated and disappeared. Later on, symptoms of hyperfunction of the accessory glands were noted. Exces-

sive atrophy of the thymus and elevation of the blood pressure were among these symptoms.

Ten of 19 pregnant rats not receiving sodium chloride died, whereas the majority of the rats provided with 1 per cent saline solution survived. Second and third pregnancies after the operation were withstood much better, whether the rats had or had not been given sodium chloride because the accessory glands had become hypertrophied. These accessory glands were seen in 66 per cent of the autopsies done within 3 months.

The number of offspring was normal but the offspring were born with a weight which was significantly subnormal. Their mortality was quite marked when the adrenalectomy was recent and its principal cause was diminution of lactation in the mother. When the operation was not recent the litter would live because the milk secretion increased.

The average weight of the suprarenal glands in the offspring of the adrenalectomized rats was increased. This could be attributed to more production of adrenotropin in the maternal pituitary gland or to stimulation of the fetal pituitary gland, or of the suprarenal glands. Although there was an increase in the weight of the glands in the average of all the groups the difference from the control group was not statistically significant; however, if the weight of the glands was calculated on the basis of the body weight the difference was a significant one.

When adrenotropin was injected into the mother her suprarenal glands hypertrophied, but those of the fetus in utero did not. This may have been due to the fact that adrenotropin does not pass through the placenta or that the suprarenal glands of the fetus are not very sensitive.

Desoxycorticosterone injected into pregnant rats prolonged gestation with subsequent excessive growth of the fetuses and difficulty in parturition. The adrenal glands of the offspring were not atrophied.

SURGICAL PATHOLOGY AND DIAGNOSIS

Young, J. S., Crulekshank, A. H., and Martin, W. J.: An Experimental Study of the Healing of Wounds, with Special Reference to the Action of Heart Extract Powder (Doljanski). *J. Path. Bact.*, Lond., 1946, 58: 63.

Four essential principles have been adduced by Doljanski and his colleagues to explain the alleged remarkable efficacy of heart extract powder in the healing of normal wounds in rats, as well as of indolent wounds in man.

1. "Extracts of certain adult organs—heart, smooth muscle, and brain—activate the growth of fibroblast colonies in vitro to a greater extent than embryonic extract of the same concentration."
2. Substances which promote the growth of fibroblasts in vitro also promote the growth of fibroblasts and other cells in vivo, as in a healing wound.
3. Heart extract powder is anaphylactogenic in man.

4. Heart extract powder possibly functions as a "wound hormone," i.e., its effect on wound healing is not local, but of a general nature.

The progress of healing in 462 experimental wounds in rabbits and guinea pigs was followed by the authors. Heart extract powder (adult sheep heart) and embryo extract powder (whole sheep embryo) applied directly to the surface of healthy wounds were found to retard the healing process.

There is no direct correlation between growth promoting activity *in vitro* and *in vivo* in so far as the healing of healthy wounds can be accepted as a criterion. Heart extract powder exercises no general or constitutional effect on the rate of healing of healthy wounds; it was not found to be anaphylactogenic in the experiments done; and it does not influence either the onset or the progress of infection.

Applied directly to the surface of a wound, heart extract powder evokes a nonspecific foreign-body giant-cell reaction, similar to that evoked by two azo dyes—Scharlach R and Sudan III—which were used as stimulants to the healing of indolent wounds.

EXPERIMENTAL SURGERY

Blalock, A.: The Effects of an Artificial Ductus Arteriosus on Experimental Cyanosis and Anoxemia. *Arch. Surg.*, 1946, 52: 247.

Studies were performed on dogs in an effort to determine whether the creation of an artificial duc-

tus arteriosus would be helpful in the treatment of pulmonary stenosis or atresia in patients. Attempts to produce the desired degree of pulmonary stenosis in dogs which would simulate conditions in the human being were unsuccessful.

The author made the observation that the removal of lobes of one or both lungs and the anastomosis of the severed proximal ends of the pulmonary artery and vein were the most satisfactory procedures to reproduce conditions of oxygen unsaturation, simulating those which were found in patients with pulmonary stenosis.

Six animals withstood the operative procedure necessary to create arterial oxygen unsaturation and accomplish a successful simulation of ductus arteriosus. In 2 of the animals, only a slight increase in arterial oxygen saturation occurred following the making of an artificial ductus, but in the 4 others there was a significant elevation of arterial oxygen saturation. This increase was due to the passage of a greater quantity of blood which was not fully oxygenated through the pulmonary capillaries.

Although the experimentally produced condition was different from that seen in patients with the tetralogy of Fallot, these studies strengthened the impression that an increase in pulmonary blood flow by the creation of an artificial ductus arteriosus is beneficial in situations of diminished pulmonary blood flow and improper oxygenation as seen in patients with pulmonary stenosis or atresia.

SUBTOTAL ESOPHAGECTOMY WITH HIGH INTRA- THORACIC ESOPHAGOGASTRIC ANASTOMOSIS IN THE TREATMENT OF EXTENSIVE CICATRI- CIAL OBLITERATION OF THE ESOPHAGUS

RICHARD H. SWEET, M.D., F.A.C.S., Boston, Massachusetts

THE majority of patients who have suffered extensive chemical burns of the esophagus have usually been dependent upon repeated dilatations by bouginage or ultimately upon gastrostomy feeding to overcome the obstruction which inevitably follows healing by cicatrization. The inconvenience and suffering which attend the application of these methods make these unfortunate patients eager for any more satisfactory substitute. One method of solving the problem in the intractable case has been the construction of an external subcutaneous artificial esophagus by one of the various plastic procedures. The recent wave of interest in this type of operation is partly the result of the work of Yudin, who reported 80 cases of cicatricial stricture of the esophagus treated by what he refers to as the "Roux-Herzen" type of esophagoplasty, performed usually in several stages, involving the temporary utilization of a gastrostomy. In Yudin's hands the results appear to have been satisfactory from the standpoint of low operative mortality and ultimate function.

There can be no doubt, however, that this is a formidable procedure. Furthermore, the patient is left with a distinctly abnormal relation of the parts of the upper gastrointestinal tract. The jejunum is attached, usually by a

lateral anastomosis, to the cervical portion of the esophagus, often a rather long distance above the highest level of stricture. The stomach is completely by-passed and becomes therefore nothing more than a secretory appendage of the alimentary canal, emptying by way of the duodenum and proximal end of jejunum into the lower portion of the jejunal segment which has been used for the esophagojejunal anastomosis. Although this arrangement is undoubtedly compatible with the maintenance of a normal state of nutrition, it would seem to be desirable to avoid it if possible.

Experience gained in the resection of carcinoma located in the mid-thoracic region has demonstrated that the stomach can be mobilized to such an extent that a very high intra-thoracic esophagogastric anastomosis can be performed (1, 2). By applying this principle to cases in which the growth lay at higher and higher levels in the esophagus, it has finally been established that a safe and functionally satisfactory anastomosis can be performed at the highest level within the thorax, actually behind the jugular notch of the sternum (Fig. 1). The application of this knowledge in the treatment of cicatricial obliteration of the esophagus is the subject of this preliminary report.

TECHNICAL CONSIDERATIONS

1. *Necessity for esophagectomy.* In order to obtain the complete mobilization of the stomach required to bring its fundus to the apex of the thorax where the anastomosis is to be performed, it is necessary to sever the stomach from the esophagus at the level of the cardia. It then becomes necessary to remove the esophagus, unless the theoretical possibility of reimplanting the distal end of the esophagus at a lower level in the stomach is entertained. A further reason for removing the esophagus is that an end-to-side anastomosis between the esophagus and the fundus of the stomach is easier to perform and better functionally than a side-to-side anastomosis between these two organs at that level in the chest.

2. *Preservation of blood supply.* (A) The preservation of an adequate blood supply to the level of anastomosis is easily accomplished in the esophagus provided that the level of division is high enough to reach the esophageal branch of the inferior thyroid artery. Division of the esophagus at a high level is of such importance that one should never be tempted to cut it at a lower point even if considerable length is available. The danger of sloughing of the end is too great.

(B) The maintenance of blood supply on the gastric side is dependent upon the integrity of the anastomotic intercommunicating vessels within the wall of the stomach itself. In order to free the stomach so as to relocate it with the fundus in the apex of the thorax, all the attachments excepting those in the region of the pylorus and the pyloric portion of the antrum must be divided. This involves the division of the left gastric artery, the vasa brevia, and the left gastroepiploic artery as well as the smaller anastomotic communications near the cardia from the inferior phrenic, suprarenal, and pericardiophrenic vessels, and the majority of the vessels in the gastrocolic ligament. In order to preserve the arcade of vessels on the lesser curvature side, the left gastric artery must be divided close to its origin from the celiac axis in order to maintain the communication between its ascending and descending branches. In freeing the stomach from its attachments by the gastrosplenic and gastrocolic ligaments to the spleen and colon,

care must be exerted to avoid injury to the anastomotic communications of the gastroepiploic vessels.

After the extensive mobilization of the stomach has been completed, the only source of blood supply which remains is that which comes by way of the right gastric and right gastroepiploic arteries. The distribution of blood to the fundus, where the anastomosis is to be, depends upon the integrity of the arcades along the curvatures; but the intramural communicating branches of these vessels are of equal importance. It is necessary, therefore, in handling the stomach during the course of the operation, to exert every effort to avoid trauma to its wall and to the vessels within it. Forceps and clamps should not be applied, and great care must be exerted to avoid tearing a vessel which might produce a hematoma in the gastric wall.

3. *Avoidance of stricture at the site of anastomosis.* A circular opening in the stomach wall is made so as to avoid the angles at each end of a linear incision. Of greater importance is the necessity for obtaining prompt and accurate healing of the layers of the anastomosis, especially the mucosa. All unnecessary trauma to these edges must be avoided. To accomplish this I strongly advise against (a) the use of crushing clamps on either side of the anastomosis, (b) the use of the cautery or a chemical caustic, such as carbolic acid, in cutting across the esophagus or stomach, and (c) the use of continuous sutures which of necessity tend to constrict the edges and produce necrosis of the tissue which they embrace.

4. *Details of dissection.* The amount of dissection required in performing an esophagectomy in a case of cicatricial stenosis is much less than is necessary in cases of carcinoma. In the former, nothing more than the removal of the esophagus from just above the upper limit of the lesion to the cardia is needed. In the latter, provision must be made for division of the esophagus at the greatest possible distance above the upper limits of the growth. In the stricture cases, furthermore, the lymph nodes can be ignored, whereas in the carcinoma group all the nodes which can be reached should be removed, particularly those around the lower thoracic portion of the

Fig. 1. Diagram to show the amount of dissection necessary in order to remove the entire thoracic portion of the esophagus and to free the stomach sufficiently to perform a high intrathoracic esophagogastric anastomosis at the apex of the chest. View from the left side (Case 3). Inset shows the principal blood vessels of the stomach which must be divided during the process of freeing the stomach: these are the majority of the omental branches of the gastropiploics, the left gastropiploic, the vasa brevia, and the left gastric vessels. After division of the cardia, where a few descending branches of the lower esophageal vessels are to be severed, the only blood supply which remains comes by way of the right gastric and right gastropiploic arteries.

esophagus and the two important groups of nodes which are found below the diaphragm (1).

In spite of these facts, the actual mobilization of the esophagus in a case of cicatricial stricture resulting from a chemical burn is always more difficult than it is in the average case of carcinoma. In the latter, the only difficulty which is encountered occurs at the site of the growth. In the stricture cases, however, the damaged segment is always densely adherent, making it difficult or impossible to find good planes of cleavage for the purpose of dissection. This appears to be the result of an extensive periesophagitis resulting from the burn. It is difficult also, probably as a result of the characteristics of the injury, to discover the exact upper limit of the scarred portion in the esophagus itself, so that after cutting into abnormal tissues at first it is sometimes necessary to choose a higher level for the site of division.

DESCRIPTION OF THE OPERATION

The operative procedure which has been used in the treatment of these cases is essentially the same as that which has been applied in the management of cases of carcinoma of the midportion of the thoracic esophagus (1, 2, 3). A brief outline follows:

1. Intratracheal ether oxygen anesthesia is used.
2. The patient is placed on his right side; the left arm is held forward with the hand in front of the face.
3. Intravenous infusion of saline and transfusions of whole blood are given through a hand or forearm vein.
4. The incision is made over the eighth rib on the left side with its posterior portion curved upward between the scapula and the spine. The eighth rib is resected. If the stricture begins at a high level (as in Case 3), it is necessary to divide one or more ribs posteriorly, the number depending partly on the upper

SURGERY, GYNECOLOGY AND OBSTETRICS

level of the lesion and partly on the configuration of the patient's chest, whether long or short, and the slope of the ribs.

5. The wound edges are protected with pads of gauze and a rib spreader is inserted. The lung is retracted.

6. The esophagus is then dissected free below the aortic arch. If the stricture extends above the arch, the upper thoracic portion of the esophagus is then freed through an incision in the mediastinal pleura posterior to the thoracic portion of the left common carotid artery. By working both from above and below, the portion behind the aortic arch and below the thoracic portion of the esophagus is then available for resection. During the performance of this dissection, the small branches from the aortic arch and the bronchial arteries and the usual esophageal branches from the descending portion of the aorta must be severed and tied. The thoracic duct may be severed as it crosses the esophagus just above the aortic arch. If it is injured, it must be tied so as to avoid the development of a chylious hydrothorax. (This had to be done in Case 3.)

7. The next step is the mobilization of the stomach (Fig. 1). To accomplish this, the diaphragm must be incised from close to its costal insertion laterally through the hiatus. The phrenic nerve is crushed to maintain its mobility of the diaphragm. The upper two-thirds or more of the stomach are freed by dividing the gastrocolic ligament with its numerous vessels (branches of the gastropiploics), the gastrolenal ligament containing the left gastropiploic vessels and the vasa brevia, and the gastrohepatic ligament with the left gastric vessels. The left gastric artery is cut close to its origin from the celiac axis so as to preserve the integrity of the anastomosis between its ascending and descending branches. The retroperitoneal attachments of the stomach to the diaphragm near the cardia are divided. Here one encounters several small vessels which must be tied (branches of the phrenic, pericardiphrenic, and the subprerenal arteries).

If the patient has a pre-existing gastrostomy, it can be taken down from within the

abdomen and the opening in the ante gastric wall closed with two layers of suture (Case 3).

The stomach is cut across between clamps just distal to the cardia. The proximal end is covered by tying a rubber glove or piece of rubber dam over it. The distal portion is inverted by means of two layers of fine catgut reinforced with interrupted silk sutures.

8. The esophagus can now be drawn up from behind the aortic arch and turned outward in a position convenient for the performance of the anastomosis (Fig. 2). At a high level on the fundus of the stomach a circular incision of appropriate size is made through the serosal and muscular coats. The small vessels encountered are ligated with fine silk so as to diminish as much as possible the amount of bleeding during the completion of the anastomosis. This portion of the fundus of the stomach is then placed in the apex of the chest and a three layer anastomosis is performed between the end of the esophagus where it is cut across above the level of the stricture, and the circular opening in the stomach wall which results from excising the portion previously outlined by incision through the serosa and muscularis. Interrupted sutures of fine silk are used. The sutures of the mucosal layer are placed in such a way that the knots lie within the lumen when tied.

9. The anastomosis having been completed, the stomach should be fastened within the chest by means of a series of fine silk suture (Fig. 3).

10. The edges of the diaphragm are fastened to the antral portion of the stomach where it passes through and the remainder of the opening in the diaphragm is closed with interrupted silk sutures.

11. A catheter for closed suction drainage is brought out through a small incision in a lower interspace posteriorly.

12. Closure of the chest is effected by careful anatomical approximation of the several layers using interrupted silk sutures. The lung should be fully expanded first.

POSTOPERATIVE MANAGEMENT

The handling of these cases after operation differs in no respect from that used in the

Fig. 2. Diagram to show the start of the anastomosis (as in Case 3). The esophagus has been dissected completely from the mediastinum and pulled up from behind the aortic arch. A circular incision is shown high on the anterior aspect of the fundus; a circular piece of gastric wall is to be removed at that point for the end-to-side esophagogastric anastomosis. The site of transection of the esophagus for the anastomosis is indicated. Note that the duodenum has been drawn to the left and upward by the displacement of the stomach into the chest; the pylorus then comes to lie just below the diaphragm.

Fig. 3. Diagram to show the anatomical relations of the viscera after the completion of the anastomosis (as in Case 3). The anastomosis lies opposite the jugular notch. The stomach is in front of and somewhat lateral to the aortic arch. It lies behind the hilum of the left lung and against the vertebral column and descending aorta. The diaphragm has been sutured around the stomach just proximal to the pylorus. The remainder of the diaphragmatic incision has been closed. The stomach has been fixed in the chest by means of interrupted sutures of fine silk to the parietal pleura.

carcinoma group. Patients who have strictures from chemical burns are more likely, however, to be much younger than those who suffer from carcinoma and their recovery is therefore somewhat more prompt and less complicated.

REPORTS OF CASES

Three patients who had suffered cicatricial obliteration of a large portion of the esophagus as a result of chemical burns were treated by radical esophagectomy. In 2 of these the upper limit of the lesion was low enough to make it possible to perform the anastomosis a short distance below the arch of the aorta. In the third, the proximal extent of the obstructed area was so high that the anastomosis when completed lay behind the level of the jugular notch. In this case a subtotal esophagectomy was performed. That such a high level of intrathoracic esophagogastric anastomosis is

possible will be appreciated by considering the fact that the apex of the thoracic cavity rises several centimeters above the level of the first rib. Thus a high anastomosis, which on first thought might appear to be in the neck, is actually within the thorax at its highest portion.

CASE 1. F. J., MGH 323121, male, aged 18 years, was admitted to the Baker Memorial Hospital on December 12, 1943, because of difficulty in swallowing, present since an early age. The exact nature of the injurious substance which this child swallowed was never discovered, but the characteristics of the injury to his esophagus were in every respect consistent with the ingestion of a solution of lye or some other corrosive substance. Dilatation of the esophagus had been performed on three separate occasions with temporary improvement, but each time he had again gradually become unable to swallow anything except liquids. He had lost 18 pounds in the 2 weeks immediately before he was seen.

Physical examination showed a tall, thin, malnourished, underdeveloped boy with a moderate

Fig. 4. Case 1. Roentgenogram of barium filled esophagus before operation. Lowest level of apparently normal esophagus is in the midthorax. There is almost complete obliteration of the lumen in the lower third.

Fig. 5. Case 1. Roentgenogram obtained after ingestion of barium after operation. The upper half of the stomach lies within the chest. The site of anastomosis is shown in the midthoracic region. It should be noted that the peristaltic waves observed along the lesser curvature of the stomach are the result of the inversion of the cardia. The anastomosis is at the apex of the fundus.

pectus excavatum. Examination was otherwise negative. Blood pressure was 110-60.

Roentgen examination revealed a stricture of the lower third of the esophagus beginning at approximately the level of the inferior pulmonary vein and extending to the cardia.

Photo. hemoglobin was 14.5 grams, white blood count 7700. There were 64 polymorphonuclear leukocytes, 3 large lymphocytes, 20 small lymphocytes, 8 monocytes, 3 eosinophils, and 2 basophils. The red blood cells appeared fairly normal and the platelets were slightly increased. The nonprotein nitrogen was 20 milligrams per cent. The urine was normal. On December 20, 1943, a resection of the esophagus with esophagogastric anastomosis was performed. A long oblique incision was made across the left side of the chest and the ninth rib was resected normal. There were no adhesions. The lung appeared normal. The mediastinal pleura was incised behind the hilum of the lung, and the esophagus was gently freed. The area of stricture was identified opposite the level of the inferior pulmonary vein and extended from that point toward the cardia for a distance of several centimeters. This portion of the esophagus was rigid, thickened when palpated, but not very abnormal in appearance. When this area was dissected up, however, it was found that the outer coats of the esophagus were considerably thickened with scar tissue and the right vagus nerve was caught in scar tissue and

could not be freed. The fibers of the left vagus nerve were multiple and it was impossible to preserve more than a few of them.

The esophagus was cut across below the level of the stricture. The point of division actually went through the lower margin of this strictured area and in order to determine how high the lesion went, the way it was incised with the scissors. In this area, where the esophagus was completely denuded of mucous membrane, had a long tongue-like projection on the right posterior aspect of the lower which went up to a point above the level of the inferior pulmonary vein. The esophagus was then cut across obliquely, the highest point where this upward extension was and the lowest point being on the opposite side, namely the lateral aspect. The distal inverted by means of a pursestring suture of 1/4 reinforced with a row of mattress sutures.

The diaphragm was then opened through the hiatus. The attachments of the stomach to the diaphragm were freed. The vasa brevia were divided and in this way it was not necessary to remove the spleen. The stomach was long and it was therefore relatively easy to bring the fundus of the

stomach high in the chest. It was necessary, however, to divide the branch of the left gastric artery which extends toward the cardia. When this was done the fundus could be pulled up to the level of the aortic arch. A high esophagogastric anastomosis was then carried out, three layers of sutures being used. When completed the anastomosis lay above the inferior pulmonary vein at the level of the left main bronchus. The stomach was suspended in its new position by means of a row of sutures between it and the pleura along the side of the vertebral column.

The cut edge of the pulmonary ligament was sutured to the stomach. The diaphragm was then sutured around it so as to prevent herniation of other viscera and the remaining divided portion of the diaphragm was sutured to itself. The point at which the diaphragm was brought around the stomach was in the region of the antrum, not more than 4 inches proximal to the pylorus which had been pulled upward.

On pathological examination of the specimen a diagnosis of nonspecific ulceration and stricture formation was made.

The postoperative course was completely uneventful. Sulfadiazine, started on the day prior to operation, was omitted on the fifth postoperative day and he was discharged from the hospital in excellent condition on January 7, 17 days following operation. Roentgen examination showed a well functioning anastomosis just below the aortic arch.

The patient has reported for follow-up examinations at intervals since operation. He has no discomfort on swallowing. He has gained weight. He is active and leads a perfectly normal life. He experiences no dyspnea and no subjective symptoms which might be associated with the presence of his stomach in the chest except that sometimes after a large meal he has an awareness of his heartbeats.

CASE 2. R. C., MGH 453847, male, aged 5 years, was admitted to the Massachusetts General Hospital on August 28, 1944. In March of 1944 he had eaten some ice cream which had fallen into paint cleaner containing lye. He received burns about the mouth and tongue and was quite ill and unable to take food by mouth for a while. Subsequent to this he had been unable to eat anything except semisolid food. Roentgen examination in June had revealed a stricture of the esophagus and bouginage was carried out at weekly intervals during July and August. He was apparently well otherwise. He had a good appetite and ate well, but regurgitated almost everything he ate.

Physical examination showed a small, slender, male child in no distress. Nothing abnormal was found. Blood pressure 90/65.

Roentgen examination showed a stricture of the lower esophagus 10 centimeters in length. The upper margins were funnel-shaped. No definite ulceration was seen. The stomach was markedly dilated and there was delayed emptying, the cause of which was not determined.

Fig. 6. Case 2. Preoperative roentgenogram obtained after ingestion of barium, showing the stricture in the lower third of the esophagus. The proximal portion is dilated.

Laboratory investigation revealed a nonprotein nitrogen of 23.0 milligrams per cent, protein 6.4 milligrams per cent, and chloride 104.0 mcg/l. The white blood count was 9600, photo. hemoglobin 15 grams, red and white blood cells normal, platelets normal.

After a period of preoperative preparation including the administration of sulfadiazine and a transfusion, a transthoracic partial esophagectomy with esophagogastric anastomosis was performed on September 9, 1944. The chest was opened by means of an intercostal incision between the eighth and ninth ribs. In order to obtain better exposure the eight, seventh, and sixth ribs were divided posteriorly. The lower esophagus from the cardia upward for about 2½ inches was apparently normal. From this point up to the level of the left main bronchus there was a hard thickened area which was very adherent by chronic inflammatory adhesions to the surrounding mediastinal structures. Above this, for a distance of an inch and a half below the aortic arch, the esophagus appeared normal.

After freeing the esophagus sufficiently to make resection possible, the diaphragm was opened. The phrenic nerve was crushed. The stomach, which was large, was freed by dividing the left gastroepiploic vessels and the vasa brevia. There were some in-

SURGERY, GYNECOLOGY AND OBSTETRICS

Fig. 7. Case 2. Roentgenogram obtained soon after operation showing the stomach high in the thorax and distended with air. Fluid level is within the stomach.

Fig. 8. Case 2. Lateral view same day as Figure 7 showing air-filled stomach in the chest. Fluid level is within the stomach.

inflammatory adhesions posteriorly which made the left gastric artery were divided. The esophagus was cut across just above the cardia and the stump was inverted into the stomach. Two layers of silk three layer, fine silk esophagogastric anastomosis was carried out above the level of the inflammatory stricture, and the diseased area was resected.

The fundus of the stomach was fixed in the chest by means of a number of sutures so as to prevent any pull upon the anastomosis. The pylorus was inspected and found to be apparently normal. The chest wall was closed around the stomach. The pericostal sutures of catgut in the first layer and interrupted silk in the remaining layers. No drainage was employed.

On pathological examination a diagnosis of chronic inflammation with ulceration was made. The patient's recovery from the operation was good. Chemical balance was well maintained. He received 1 ounce of water each hour on the second day following operation. Sulfadiazine had been begun on the day prior to operation and was continued until the fifth postoperative day. Roentgen exami-

nation of the chest 3 days after operation showed collapse of the left lung. This expanded gradually but completely. Roentgen examination following swallow of barium prior to discharge from the hospital showed a normally functioning stomach and marked improvement in the passage of barium through the pylorus into the duodenum. He left the hospital in good condition on September 30, 1911, 21 days after operation.

Since operation he has had no difficulty in swallowing. His weight gain has been slow, but investigation has revealed that his eating habits are poor and that the other members of his family are all of slight build.

CASE 3. O. C., MGH 496561, female, aged 21 years, was admitted to the Massachusetts General Hospital on October 11, 1915. She had been unable to swallow anything since January 21, 1912, when during a period of postpartum depression she had attempted to commit suicide by swallowing about a tablespoonful of Drano, which is a solution of lye used for cleansing drain pipes. Frequent dilatations had been attempted but were unsuccessful. After one acute dilatation the patient showed evidence of mediastinitis which resulted in the development of acute empyema on the right side. She recovered after rib resection for drainage. In March, 1914, a gastrostomy had been performed by means of

Fig. 9. Case 3. Preoperative roentgenogram after ingestion of barium. The upper level of the stricture is at the jugular notch. The entire thoracic portion of the esophagus is involved in extensive cicatrization and cicatricial obliteration. Note the shadow at a higher level in the neck thought at first to be barium within a diverticulum, but later proved to be the result of obstruction produced by a cicatricial web at that level.

which she could feed herself, but she was unable even to swallow her saliva and was kept awake at night by continual cough caused by this difficulty.

At the time of first examination, in July, 1944, she had been extremely thin, but in the interval between then and the present admission she had gained some 15 to 20 pounds. Physical examination was negative except for the presence of a scar of empyema drainage, performed in 1942, and an epigastric vertical scar with a 0.5 centimeter gastrostomy opening in excellent condition. Blood pressure was 108/94.

Roentgen examination revealed complete obstruction of the esophagus beginning at the level of the jugular notch where there was a funnel-shaped gradual narrowing. Below this point only a trace of barium could be seen to pass through. There was a shadow at the junction of the hypopharynx with the esophagus which was thought to indicate the presence of a pulsion diverticulum.

Laboratory studies showed a nonprotein nitrogen of 23 milligrams per cent, total protein 7.3 milligrams per cent, and a chloride of 94 milligrams per cent. The white blood count was 7200 and the Tall-

Fig. 10. Case 3. Roentgenogram outlining the stomach after completion of the second operation. The anastomosis lies at the level of the jugular notch.

quist hemoglobin 80 per cent. The urine was negative.

A transthoracic esophagectomy with a high esophago-gastric anastomosis was performed on October 16. The left side of the chest was opened and the eighth rib was resected. In order to gain adequate exposure for a subtotal esophagectomy, it was necessary to divide the seventh, sixth, fifth, and fourth ribs posteriorly. The mediastinal pleura was then incised and the esophagus was exposed. It was surrounded everywhere by a dense layer of thick fibrous tissue. This fibrous tissue, which prevented the development of planes of cleavage in which a dissection could be carried out, was thicker in some places than in others. It was particularly dense and difficult to dissect just below and behind the aortic arch. At this level, after a long and painstaking dissection from both above and below the arch, it was finally discovered that the esophagus had narrowed down to an extremely small circumference, having almost no evidence of a lumen at this level. Because it was so difficult to free it from the bronchus and lower end of the trachea at this point, the esophagus was finally cut from below and above the arch, a small portion being left attached. In this case the thoracic duct was inadvertently cut across, but it was recognized and each end was tied.

SURGERY, GYNECOLOGY AND OBSTETRICS

The diaphragm had been previously opened so as to free up the stomach. The freeing of the stomach was completed by cutting the vasa brevia, the gastroepiploic and the left gastric vessels, and incising down the gastroepiploic and gastrohepatic ligaments. The lower end of the esophagus was cut across. The distal stump was inverted with a silk pursestring suture reinforced with several mattress sutures of silk. The proximal end of the esophagus was pulled out from behind the aortic arch, and the upper limit of the stricture was found to be as shown by the x-ray at or slightly above the level of the jugular notch. This site necessitated pulling the fundus of the stomach up to the base of the neck. At this level a difficult three-layer anastomosis was performed between the cut end of the esophagus and the circular edge of stomach which remained after the excision of a small round piece. The posterior portion of the cut edge of the esophagus had some scar tissue in it, anteriorly the wall was more normal. After the anastomosis had been completed, the stomach which had been brought all the way up the length of the chest was sutured with a row of fine silk sutures extending from the apex of the chest down to the diaphragm. The diaphragm was then closed around the lower end of the stomach just above the displaced pylorus. Penicillin was inserted both above and below the diaphragm. The wound was then closed in layers by means of silk, after a catheter was brought out through one of the lower interspaces.

On pathological examination a diagnosis of acute and chronic inflammation with ulceration was made. The patient's recovery from operation was good, but it was realized a week later that she still could not swallow as well as she should. At first she was able to swallow fluids well, but finally even this was difficult. There was obstruction to the passage of a Levine tube at the level of the sternal notch. An attempt was made at this time to have her swallow barium, but she was unable to do so. A roentgenogram obtained after the administration of a swallow of barium had on all previous examinations shown a shadow which was thought to indicate the presence of a pulsion diverticulum of the pharyngoesophageal junction. An attempt to visualize the anastomosis through an esophagoscope was unsuccessful. It was therefore concluded that there must be a stricture at the site of the anastomosis. It was decided to explore this by opening the esophagus through the diverticulum and to correct the difficulty by manipulation through this opening.

On December 11 an oblique incision was made along the course of the anterior border of the sternomastoid muscle on the left side. The usual exposure to remove a diverticulum of the esophagus was then obtained, going in above the omohyoid muscle. There was no diverticulum to be found. A longitudinal incision was therefore made through the wall of the esophagus and on palpation downward an obstruction was met about halfway down the neck. The incision was then enlarged down to the jugular

notch and the entire length of the esophagus was exposed. In doing this it was necessary to divide the inferior thyroid vessels, the ansa hypoglossi nerve, the omohyoid muscle, and the lower attachments of the pretracheal muscles. The exposure was excellent.

The esophagus was then incised below the obstructed point, and at this level the lumen was entirely open and the mucosa normal. By palpation downward through the opening the index finger could be easily passed through the esophagogastric anastomosis which was not obstructed. The two strictures were then connected and the web-like stricture which had almost completely obstructed the lumen was incised and the resulting mucosal edges were sutured so as to restore the lumen to a normal diameter. Silk was used. The longitudinal incision was then sutured with three layers of silk, one in the mucosa, one drawing the edges of the muscularis together, and a third folding it in. Before this was done a soft Bardenheer catheter was inserted with the funnel-shaped end downward through the anastomosis, the tip end upward into the mouth, to be brought out through the nose after completion of the operation. Penicillin was then inserted in the deep spaces of the neck and behind the esophagus, and the wound was closed in layers with silk technique without drainage.

The patient's convalescence following the second operation was completely uneventful. She was fed a liquid diet through the catheter until the tenth day when the catheter was removed. From that time on she was gradually allowed more and more food until the time of her discharge from the hospital when she was taking a liberal soft solid diet. She was discharged in excellent condition on the eighteenth day after the second operation. Roentgen examination following a swallow of barium showed the anastomosis to be functioning with no difficulty (Fig. 10). There was no delay in the passage of barium and the previously described narrowing of the cervical portion of the esophagus was no longer present. She has done well since returning home. She has reported by letter recently that she has no difficulty swallowing and that she can eat anything ever

RESULTS OF OPERATION

All three patients made a complete recovery, complicated in the third case by the necessity for a secondary operation for the relief of a previously unsuspected web-like stricture in the cervical portion of the esophagus. All have resumed a normal existence. The first patient, as a result of the operation has been able to eat normally for the first time since infancy. The second patient appears to be developing in a normal manner consistent with his age although he does not weigh as much as most children of his age.

The other two have gained in weight. In no case is the patient aware, so far as subjective sensations are concerned, that the stomach lies within the chest. The first patient, a rather high strung individual, occasionally experiences attacks of palpitation, usually as a result of excessive exertion soon after eating. He has been able however, to engage in competitive games and athletic exercises at school. All three patients are apparently perfectly well and free from physical handicaps.

SUMMARY AND CONCLUSIONS

The advantages of esophagectomy followed by the performance of an esophagogastric anastomosis are obvious and important. First, the procedure can usually be carried out in one stage. This not only diminishes the amount of discomfort and annoyance to the patient, but it should also shorten the period of hospitalization. In the second place, there is less interference with the normal relation of the parts of the upper alimentary tract to each

other. The food is delivered directly into the stomach instead of into the jejunum. Thus the amount of food which can be taken at one time is more nearly normal. From the subjective standpoint the patient is more comfortable and psychologically has the feeling that he has been restored functionally at least to a normal state. In cases of intractable stricture of the esophagus resulting from chemical burns, therefore, an esophagectomy followed by a high intrathoracic esophagogastric anastomosis is superior anatomically, physiologically, and psychologically to any form of external esophagoplasty as a method of restoring the functional continuity of the upper alimentary canal.

SUPPURATIVE CHOLANGITIS COMPLICATING SIDETRACKING OPERATIONS OF THE BILIARY TRACT

JERRY ZASLOW, M.D., and VIRGIL S. COUNSELLER, M.D., F.A.C.S., Rochester, Minnesota

AS a result of obstructive lesions of the extrahepatic bile ducts, it often becomes necessary to perform various types of sidetracking operations in order to divert the biliary stream. While this usually proves to be a safe and efficient procedure, serious complications due directly to the operation sometimes occur. By far the most hazardous complication is suppuration in the biliary tract.

REVIEW OF THE LITERATURE

In 1882 Winiwarter performed the first sidetracking operation for obstructive jaundice in man, anastomosing the gall bladder and colon in seven stages over a 17 month period. Six years later, Oddi reported on his use of cholecystogastrostomy in dogs, noting that it was safer than cholecystenterostomy, since Harley and Gaston had 6 deaths in 7 cases in which the latter operation was done on dogs. The same year Riedel reported the first choledochoduodenostomy in man, and 2 years later Mayo-Robson (34) the first cholecystenterostomy, but in both cases the patients died. The first successful choledochoduodenostomy and cholecystogastrostomy in man were performed by Sprengel in 1891 and Wickhoff and Angelberger in 1893, respectively.

In general the experimental evidence points to the fact that ascending infection in the bile ducts occurs in almost all cases in which direct cholecystogastrostomy or cholecystenterostomy is performed in dogs. Usually the severity of the infection is greatest when the colon is used and least when the duodenum or stomach is used (3, 12, 20, 22, 23, 47). By destroying all lymphatics communicating between the gall bladder and the liver in dogs, Lehman showed that the infection was due to regurgi-

tation from the gastrointestinal tract and not necessarily to spread via the lymphatics. Gentile alone presented experimental evidence to show that hepatitis or cholangitis does not complicate cholecystogastrostomy in dogs, while Weinberg, Wallin, and Binger noted the absence of this complication in monkeys.

The clinical evidence is not so conclusive. Michaux was one of the first to report a case of cholangitis following cholecystoduodenostomy. The inflammation developed 4 weeks after operation, and the patient died 1 month later. Kausch reported 2 cases in which cholecystojejunostomy was done for carcinoma of the pancreas and in which suppurative cholangitis developed 9 months and 4 months later, respectively. Wangenstein described in detail 1 case in which cholangitis developed 8 months after operation. Roeder reported 6 cases in which he performed sidetracking operations. In 2 of these cases, in which he did cholecystoduodenostomy, the patients did well, but of 4 patients who underwent cholecystogastrostomy, 2 died, one 10 days, and the other 74 days after operation. In both cases chills, fever, and jaundice developed. Mason and Baker reported a death due to abscesses of the liver 2 years after cholecystogastrostomy had been done. Eliason and Johnson noted that ascending infection was a complication of cholecystogastrostomy or cholecystoduodenostomy frequent enough to prevent their indiscriminate use. Brunschwig (5) and Whipple (42) also observed cholangitis after cholecystojejunostomy. Puestow, writing on spontaneous biliary fistula, refuted the belief that the formation of internal fistula relieved symptoms referable to the biliary tree. In the 16 cases on which he gave data, all but 4 patients had chills and fever, and all but 1 had recurrent jaundice. In the 1 case without jaundice the cystic duct

†On the basis of 1 to 4, in which 1 designates the least and 4 the greatest concentration of bile

was obliterated by inflammatory fibrosis, thus protecting the biliary tract from regurgitation of intestinal contents with resulting cholangitis. Colp recently reported that in 2 of 5 cases in which he performed hepaticoduodenostomy, chills and fever developed. In 1 case he did a Billroth II procedure to divert the gastric stream but symptoms continued.

In contrast to the foregoing unfavorable résumé, Mayo-Robson (35) expressed the belief that cholecystenterostomy is a safe procedure, basing his conclusions on 64 cases. White expressed a similar opinion for cholecystogastrotomy after his 3 patients did well. Babcock reported an additional 130 such operations, without evidence of postoperative ascending cholangitis. Moynihan cited 39 of his own cases and did not mention the complication. Steel went so far as to state that the gall bladder resists infection from the bowel. He expressed a preference for cholelithotomy followed by cholecystogastrotomy rather than cholecystectomy in cases of cholelithiasis. Judd and Parker, in discussing palliative procedures for carcinoma of the pancreas, stated, "It is expected that infection will result from direct extension or by the periductile lymphatics; this would not be likely to occur within the life expectancy period." Yet, in the same report, they stated that 2 of 62 patients who underwent operations for stenosis of the bile ducts and 1 of 9 patients on whom operation was performed for carcinoma of the bile ducts had chills, fever, and jaundice in the

postoperative period. Oppenheimer and his co-workers had no cases of cholangitis in their 34 cases of cholecystogastrotomy. Bardeleben, Kehr, and Bernhard also expressed the opinion that cholangitis is no serious objection to cholecystenterostomy, and Lehner stated his belief that cholangitis, even when it does develop, is not a serious complication, since it is only temporary.

Recently, a patient who had suppurative cholangitis shortly after direct cholecystogastrotomy had been performed for obstructive jaundice, came under our care.

REPORT OF CASE

A white man, 64 years of age, was admitted to the Mayo Clinic on March 31, 1945, with a history of abdominal pain for 1 year and jaundice for 6 months. The past history revealed only persistent glycosuria for 8 years. The present symptoms had started in July, 1944, with vague distress in the upper part of the abdomen, not related to meals and rather persistent. There were associated mild anorexia and some loss of weight. The patient stated that at that time he had been put on a special diet and given 40 units of protamine-zinc insulin and 20 units of regular insulin parenterally daily, since his physician had felt that his diabetes was responsible for the symptoms. In September, 1944, icterus, light stools, dark urine and intermittent vomiting developed. The jaundice cleared somewhat over the following weeks. As the result of roentgenologic studies a nonfunctioning gall bladder and a normal stomach had been reported. However, the symptoms continued, becoming worse 2 weeks before the patient came to the clinic. In addition, intermittent diarrhea developed.

Physical examination on admission to the clinic revealed severe icterus, an enlarged, tender liver, and

Fig. 1. Very mild constitutional reaction to suppurative cholangitis following cholecystogastrostomy. Patient died on twenty third postoperative day. Essential laboratory work is also included.

a palpable gall bladder. The temperature, pulse, and respirations were normal. The essential laboratory findings are included in Table I. On the basis of roentgenologic examination considerable dilatation of the stomach and first portion of the duodenum and a duodenal deformity in the region of the ampulla of Vater suggesting a neoplasm, not primary in the duodenum, were reported.

Operation was performed on April 6, 1945. A mass involving the head of the pancreas and the medial wall of the duodenum was found. This was producing obstruction of both the duodenum and the biliary tract. The liver was enlarged, very firm, and deep green. The gall bladder and the common duct were dilated considerably. There was some ascites. Posterior gastroenterostomy and direct cholecystogastrostomy were performed. The bile was clear and green. Five grams of sulfanilamide were left in the upper part of the abdomen.

The postoperative course is shown in Figure 1. The temperature was normal until the eleventh day, when it rose to 99.6 degrees—100 degrees F. and remained at this level for 5 days. The patient experienced a chill on the fifteenth day and the temperature rose to 100.4 degrees F. However, it promptly returned to normal. It rose again to 99.4 degrees F. on the seventeenth day for a single reading but soon returned to normal and remained normal or subnormal until death which occurred on the twenty-third day.

On the fifth day edema of the legs and feet, attributed to hypoproteinemia, developed. Consequently, the patient was placed on a high protein

diet supplemented by oral administration of 54 grams of amigen (an enzymatic hydrolysate of casein), daily. There was some clearing of the edema. On the eighth day there was drainage of bile-stained ascitic fluid from the incision, and the patient complained of pain in the right shoulder attributed by us to diaphragmatic irritation, possibly from a leak at the anastomosis, which did not heal well as a result of the hypoproteinemia.

The jaundice at first seemed to be clearing and the stools regained color. On the eleventh day, when the temperature rose, the stools again became acholic and the icterus deepened. The serum bilirubin level rose to 60 milligrams per 100 cubic centimeters direct, remaining at this level until death. It was felt that the increasing jaundice was due to a stricture at the site of cholecystogastrostomy, following a leak on the eighth day.

At necropsy the interesting findings were limited to the upper part of the abdomen. The liver was enlarged and brownish green and its surface was studded with small abscesses. These were most numerous on the diaphragmatic and posterior surfaces. The intrahepatic and extrahepatic bile ducts were greatly dilated and were filled with thick yellow pus and granular material. The pancreas had a carcinoma in the head obstructing the pancreatic and common bile ducts. There was evidence of infection around the head of the pancreas. The anastomoses were patent and the suture lines intact. Microscopic examination of the organs confirmed the gross anatomic impressions and also revealed a few small metastatic regions in the liver.

Choledochojejunostomy	1	0	0
Totals	16	2	14

*These cases are included among the cases in the preceding column.

The true nature of things was not fully appreciated before the death of the patient. It was felt that there was either a stenosis of the anastomosis between the gall bladder and the stomach or a metastasis in the hilus of the liver producing further obstruction of the biliary tract. The relatively normal post-operative temperature, the only slightly elevated neutrophil leucocyte count and the absence of more than only a single mild chill all argued against suppuration. That the infection developed following the operation is supported by the finding of clear bile in a dilated, although otherwise normal biliary tract at the time of operation, whereas at necropsy not only was the tract dilated but the walls were thickened and the lumen was filled with thick creamy pus. It is well to recall that the anastomoses were patent. *While in most cases of stricture of anastomoses of this type, cholangitis does develop, the formation of stricture is not necessary for the development of cholangitis.* In a significant percentage of cases in which necropsy was done following death at variable times after sidetracking operations, cholangitis of greater or less degree was present without an obstruction.

While it may appear that the absence of chills, fever, and increasing jaundice in the postoperative period would argue against inflammation in the biliary tree, this is not necessarily true. Walters and Snell stated that "the gravity of the symptoms is not always an index of the degree of suppuration, and in many cases extensive purulent infection

of the biliary passages may develop with only minor systemic manifestations. This is especially true of the cholangitis which may develop in association with stone or stricture. It has been observed many times that actual suppuration in the bile passages may occur without fever."

This fact may well explain the discrepancy between the experimental evidence of almost constant suppuration and the clinical reports by many physicians of the absence of any infection. In experimental work all the animals are subjected to careful postmortem study and no cases of cholangitis are overlooked, whereas only a very small number of human beings are ever so studied. Only at the operating table or at necropsy can a definite diagnosis be established. It is very likely that in many cases that follow a course similar to the one presented here, or in which at first the patient appears to do well after sidetracking operations for malignant obstruction of the biliary tract and then progressive jaundice attributed to hepatic metastasis develops, there is in reality suppurative cholangitis, never recognized because necropsy is not performed after death. In view of this, all figures for the incidence of cholangitis must be looked on as lower limits of the actual incidence.

INCIDENCE OF CHOLANGITIS

Following the case reported here, it was decided to attempt to determine, as accurately

TABLE IV.—FREQUENCY OF CHILLS AND FEVER IN EIGHTY-TWO CASES OF SIDETRACKING OPERATIONS FOR BENIGN OBSTRUCTION OF THE BILIARY TRACT (1937-1938)

as possible, the incidence of cholangitis developing after sidetracking operations for malignant obstruction of the biliary tract. It was also felt that we might determine how often chills and fever associated with malignant obstruction of the common bile duct were relieved by such procedures. The only way, short of operation or postmortem examination, that we know by which cholangitis after sidetracking operations can be suspected is on the basis of the symptoms of chills and fever, with or without associated jaundice, leucocytosis and increased sedimentation rate. The presence of chills and fever associated with jaundice or biliary colic before operation is also presumptive evidence of cholangitis. We, therefore, used chills and fever as specified as the criterion by which we diagnosed cholangitis, when we were certain that the symptoms were not due to any other factors. All such cases in which operation was performed during the years 1937 to 1943, inclusive, were chosen. There were 209 such cases. In addition, a series of cases of benign lesions, during 1937 and 1938, was investigated to compare the results. There were 82 such cases. The findings are summarized in Tables II to V, inclusive.

It is noted from an analysis of these figures that 88 per cent of these patients who had preoperative chills and fever associated with malignant obstruction of the bile ducts were

TABLE V.—RESULTS OF EIGHTY-TWO SIDETRACKING OPERATIONS FOR BENIGN OBSTRUCTION OF THE BILIARY TRACT (1937-1938)

*Percentage of cases in each group in which there were no chills and fever before operation.

cured of these symptoms, whereas 7 per cent of those who, before operation, had not had symptoms suggesting cholangitis manifested such symptoms at variable times after operation. In addition, in 14 cases cholangitis developed following, or as a result of the operative procedure, and in only 2 cases in which chills and fever had been present preoperatively did these symptoms continue postoperatively. A similar observation is made when dealing with the benign strictures of the common duct, 65 per cent of patients (17 of 25) being relieved of their symptoms by operation and 32 per cent (18 of 57) manifesting these as new symptoms after operation. This latter percentage is considerably higher than that in the malignant group. However, the average life expectancy of the malignant group was very short (a matter of months), whereas that of the benign group was much longer. Is it not likely that, had the patients who had malignant lesions lived longer, the figure would have been higher? This may be surmised, since many of the patients in the benign group who manifested chills and fever did not do so until, in some cases, years had elapsed.

It is also observed that just as many patients in the malignant group had symptoms after operation as before; namely, 16. However, only 2 patients fell into both groups. In

other words, 14 patients were cured of their symptoms and 14 others did not have these symptoms until after operation. Unless the figures are broken down in this manner, this fact is not recognized. The usual observation is merely that cholangitis is present just as often before, as after operation. The most significant observation, then, is missed.

It is rather difficult to explain why the same operation should relieve symptoms in some cases and produce them in others. This may be due to the fact that the patient who has cholangitis associated with obstruction has acquired some resistance to infection, and when the obstruction is overcome and internal drainage is established, resolution takes place. On the other hand, the patient who has not had previous cholangitis suddenly has his dilated biliary tract exposed to intestinal bacteria, in the absence of any previous immunization. Rapid suppuration in such a biliary system follows. This explanation of regurgitation as the cause for postoperative cholangitis is more likely than stricture formation alone, since there is no reason why strictures should develop more often in patients without cholangitis before operation than in those who have cholangitis before operation.

The conclusion that we draw from our analysis of the figures is that if there were means of preventing such postoperative complications from developing, the value of sidetracking procedures would be enhanced manifold. This is even more true for the benign group, in which the patients are often young, the operative mortality rate is not prohibitive, and the patients do live for a reasonable time after operation.

PREVENTION OF POSTOPERATIVE CHOLANGITIS

Attempts to prevent cholangitis from developing after anastomotic operations between the biliary tract and the intestine or the stomach are not new. In 1904, Monprofit suggested the performance of cholecystenterostomy in the form of a Roux procedure, dividing a loop of jejunum, using the distal segment for the anastomosis and then connecting the proximal to the distal loop further down as an end-to-side procedure. Whipple(43) also used this operation, and in one such case

in which the patient died 6 months later, no cholangitis was found at necropsy. Eliot expressed the opinion that the use of cholecystogastrostomy rather than cholecystenterostomy would reduce the incidence of cholangitis. However, Mason was the first to report anastomosing the gall bladder to the stomach in such a manner that the former tunneled its way through the wall of the stomach before it reached the gastric lumen. In this way gastric peristalsis would obliterate the lumen of the gall bladder and thus prevent regurgitation of gastric contents. Roeder, DeBakey and Ochsner, Glassman, Zollinger, and McCaughan and Purcell reported favorably on various modifications of the Mason procedure. Although the operations were done on only a few patients, these authors noted the absence of cholangitis in large numbers of dogs on which this operation was performed, while the incidence of cholangitis was high in dogs on which direct cholecystogastrostomy was performed.

In 1941, Hunt and Whipple(43) suggested using the common bile duct rather than the gall bladder, and anastomosing it to the jejunum. In their opinion the common duct would be more resistant to infection since the pressure within it was greater than in the gall bladder. In 1943, Brunschwig, reporting a one stage pancreatoduodenectomy, performed just such a choledochojejunostomy, protecting the biliary passages still more by anastomosing the afferent and efferent jejunal loops in order to divert the intestinal stream. Orr recently emphasized another principle in performing pancreatoduodenectomy: "... location of the anastomosis between the gall tract and pancreas and the jejunum proximal to the gastroduodenostomy to prevent infection of the gall tract and pancreas." Combining several of the methods mentioned previously, Cole and Reynolds stressed the fact that choledochenterostomy should be done, and placed first in the line of anastomosis. They mentioned 2 cases in which chills and fever stopped when they interrupted, by a Roux procedure, the loop of jejunum which allowed reflux of food through a vitallium tube. They also suggested partly folding in the wall of the loop of jejunum anastomosed to the biliary tree in such a

manner as to make valves to direct the flow of contents away from the anastomosis of the biliary tract to the jejunum.

All of the procedures mentioned are concerned with preventing regurgitation of intestinal contents, the feeling being that cholangitis developing after the sidetracking operations more commonly performed is often due to direct regurgitation, rather than secondary to stricture of the anastomosis. As previously mentioned, necropsy does reveal a rather high incidence of cholangitis after the usual sidetracking operations in the absence of stricture.

As yet, not enough cases have been reported to help us to come to any definite conclusion as to the value of any of the procedures mentioned previously. Surely, the operations as usually done are far from satisfactory.

CONCLUSIONS

1. Severe suppurative cholangitis may be present in the absence of marked constitutional or local symptoms.

2. Any patient who has mild systemic symptoms in the immediate postoperative period after biliary-gastrointestinal anastomosis should be suspected of having suppurative cholangitis, in the absence of other evidence to explain these signs and symptoms. This is especially true if there is associated progressively deepening jaundice.

3. Most patients who have cholangitis associated with obstructive jaundice are relieved of their symptoms after sidetracking operation but an appreciable number of patients who previously did not have chills or fever have these symptoms after such operation. These circumstances are very likely often the result of regurgitation of intestinal contents.

4. Surgical procedures designed to prevent and relieve cholangitis following sidetracking operations for obstructive jaundice are described. The authors quoted reporting these operations stress the prevention of regurgitation of gastrointestinal contents and minimize the rôle of stricture formation in the development of postoperative cholangitis.

THE SURGICAL SIGNIFICANCE OF AORTIC ARCH ANOMALIES

ROBERT E. GROSS, M.D., F.A.C.S., and PAUL F. WARE, M.D., Boston, Massachusetts

IN spite of the complex changes which occur in the fetal vascular network, it is a remarkable provision of nature that such constancy is attained for man in the development of the normal aortic arch and its important branches. It is not surprising that this intricate maturation is occasionally disturbed and some sort of a local malformation is evolved. For more than 200 years medical literature has contained reports of aberrations in development of the arch or of the arteries leading from it. Most of the earlier observations were made by anatomists or pathologists, but within the last two decades there have been frequent attempts to correlate the complaints or the clinical findings in patients with the pathological anatomy which is later detected at the autopsy table. More recently the roentgenologist has provided techniques for recognition of many of these malformations in the living subject. It now becomes incumbent upon the surgeon to provide methods of operative relief whenever this might be required and when it appears feasible.

In the following presentation there has been no effort to discuss, or even mention, all of the anatomical variations which have been observed in the aortic arch and its major vessels. Instead, we have selected only the more common abnormalities which seem to have some possibility of surgical correction or which have been already improved by the operative procedures which are listed. Our studies in this field have been stimulated and advanced by the intelligent guidance of conferees, particularly by Dr. Sidney Farber and his aides in the pathological laboratory and by Dr. E. B. D. Neuhauser in the department of roentgenology.

In a consideration of the congenital malformations of the aortic arch, it is well to

From the Department of Surgery of the Harvard Medical School and the Surgical Services of the Children's Hospital and the Peter Bent Brigham Hospital.

begin with some sort of a classification. The following has been used as a working basis; we are cognizant of its defects and omissions, but have employed it because it affords a logical grouping from which our discussion can start.

CLASSIFICATION OF AORTIC ARCH ANOMALIES

1. Right aortic arch
 - A. Situs inversus viscerum
 - B. Right aortic arch without inversion
 1. Anterior type—arch is anterior to the trachea. Descending aorta is right-sided.
 2. Posterior type—arch passes to the left behind the esophagus. Descending aorta courses to the right of normal left side position.
 - a. Right aortic arch in which the left subclavian artery arises last from the arch and crosses behind the esophagus (Fig. 1)
 - b. Right aortic arch in which no vessel arising from the arch crosses the midline posterior to the esophagus. A vessel may pass in front of the trachea (Fig. 2)
 - c. Right aortic arch with a persistent left aortic diverticulum giving origin to the left subclavian artery and ligamentum arteriosum (Fig. 3)
2. Double aortic arch
 - A. One aortic limb obliterated
 - B. Both aortic limbs patent (Fig. 4)
3. Anomalous right subclavian artery. Arises from the left side of a normal aortic arch and crosses the midline, compressing the esophagus (Fig. 5)
4. Patent ductus arteriosus (Fig. 6)
5. Coarctation of the aorta (Fig. 7)

RIGHT AORTIC ARCH

A right aortic arch represents a persistence of the right 4th branchial artery—instead of the left one, which normally forms the fully developed arch in man. In this malformation, the aorta arises in a more or less normal way from the left ventricle and then it courses posteriorly over the right main bronchus. From here it extends in front of the trachea (in the rare "anterior type") and then con-

tinues downward behind the lung root as a right-sided aorta. In the more common "posterior type" the arch passes to the left behind the esophagus and the descending aorta continues downward—not on the right side—but in a position somewhat to the right of its normal position.

Great variations can be found in the origins and the courses of the vessels which come from a right aortic arch. We do not care to describe all of these, for fear of introducing too much confusing data. The classification which has been adopted for right aortic arch cases is by no means inclusive; it is intended to present only the more common malformations.

A. Situs inversus vicerum. These cases are possibly improperly classified under the term of "right aortic arch" since they merely represent a side-for-side reversal of the heart and its vessels. In conjunction with this may be a *situs inversus* of the abdominal organs, but it is more common to have the reversal limited to the heart and aorta. This type of anomaly usually presents no symptoms.

B. Right aortic arch without inversion.

1. *The anterior type.* The ascending aorta rises to the right over the right main bronchus, the second portion lies in front of the trachea, and the descending part passes downward to the right of the midline. Such an anomaly is rare and is encountered primarily in association with transposition of the great vessels.

2. *The posterior type.* In all of these cases the aorta extends posteriorly to the right of the trachea and esophagus, and then to the left behind the esophagus, continuing downward in a place which is a little to the right of the normal alignment. This posterior type may be subdivided into three general groups, as summarized in the classification. In each of these three divisions there are certain features in the way of esophageal or tracheal compression which probably can be recognized by roentgenologic studies in a living patient.

In group 2a, and as depicted in Figure 1, a major portion of the arch lies behind the esophagus, but in addition, the posterior wall of the esophagus above this is indented obliquely by the left subclavian artery which

has an origin low down on the back side of the arch. Furthermore, the left common carotid artery is apt to originate to the right side of the midline and to course over the anterior surface of the trachea.

In group 2b, and as shown in Figure 2, the arch lies transversely behind the esophagus and no other vessel courses in back of the esophagus. The left common carotid artery can cross in front of the trachea and compress it. Frequently, the left common carotid artery and the left subclavian artery arise from a left innominate artery (a minor image of a normal arch and vessels). The pulmonary artery, by virtue of its attachment through the ligamentum arteriosum (or a patent ductus arteriosus) to the posteriorly displaced aortic arch, is pulled backward and pushes on the trachea.

In group 2c, a general arrangement and disposition of vessels can be found as indicated in Figure 3. The important feature here is a so-called "aortic diverticulum"—of variable size—which is an outpocketing of the distal part of the arch and which gives rise to the left subclavian artery and to the ductus arteriosus (or the ligamentum arteriosum).

The various types of right aortic arch may give little or no symptoms and they are frequently of only academic interest. Eisen found 8 right aortic arches in 238 fluoroscopies of the chest for other pathology; in no case were there symptoms referable to the anomalous arch. It is possible, however, for a variety of complaints to come from these regional malformations—as is testified by many reports including those of Renander, Sprague *et al.*, Spencer and Dresser, Garland, Metzger and Ostrum, Faber *et al.*, and also by the patient described below as Case 1. There may be dysphagia, stridor, dyspnea, cyanosis, hoarseness, cough, pain in the upper chest, and vague sensations in the arms. From a study of pathologic specimens and from illustrations such as Figures 1, 2, and 3, it is clear that symptoms may be derived from the arch behind the esophagus, from the great vessels which cross behind the esophagus or in front of the trachea, from a large aortic diverticulum, or from a pulmonary artery which is held posteriorly by its attachment to the arch.

artery; *L.S.A.*, left subclavian artery; *P.D.A.*, patent ductus arteriosus; *R.C.C.A.*, right common carotid artery; *R.S.A.*, right subclavian artery.

Fig. 3. Right aortic arch with persistent left aortic diverticulum giving rise to the left subclavian artery and the ligamentum arteriosum. Frequently the aortic diverticulum is longer than is indicated here. *A.D.*, aortic diverticulum; *L.A.*, ligamentum arteriosum; *L.C.C.A.*, left common carotid artery; *L.S.A.*, left subclavian artery; *R.C.C.A.*, right common carotid artery; *R.S.A.*, right subclavian artery.

As far as surgical therapy is concerned, none has ever been attempted that we are aware of. It is permissible to surmise that relief could be afforded in some instances when the symptoms are severe enough to warrant such an undertaking. Clearly, many of the local vascular conditions cannot be changed, but at least three possibilities are worthy of consideration. Arteries (such as a subclavian or common carotid) which impinge on the esophagus or on the trachea could be divided or displaced in such a way that this pressure is relieved. An aortic diverticulum, if it is very long, could be removed (and the first part of the left subclavian artery sacrificed); in this way compression of the esophagus could be diminished. A ligamentum arteriosum (or a patent ductus arteriosus) could be divided and thus allow the pulmonary artery to fall forward and away from the trachea.

CASE 1. M. O'D., a 4 month old baby, entered the hospital because of difficulty in breathing and feeding since birth. Mucus frequently collected in the throat and gave rise to severe bouts of coughing, but the infant never became cyanotic. Excessive mucus

and coughing were more troublesome when the child was lying on her back. When she was picked up, or her position was changed, these difficulties improved somewhat. Since birth, there had been hesitation in swallowing, and this had become more marked in the month preceding hospitalization. If urged to take more than 1 or 2 ounces she invariably vomited part or all of the previously ingested feeding. Physical examination revealed a poorly developed but fairly well nourished baby. When she was disturbed, the respirations became quite noisy and there was an inspiratory crow. Roentgenographic examination of the chest revealed some peribronchitis. With a swallow of barium in the esophagus, a filling defect could be seen on its posterior wall at the level of the 3rd or 4th thoracic vertebra. The trachea was narrowed just above the carina.

The child regurgitated most of the milk which was offered; gavage was unsuccessful. Because of the precarious state of health, a gastrostomy was performed for feeding purposes. Evidence of pulmonary infection increased and, on the fifth postoperative day the baby died.

Postmortem examination was confined to the chest. There were present a diffuse, severe bronchopneumonia and early bilateral empyemas. The foramen ovale was still patent. The aortic arch and its respective vessels were found as indicated in Figure 2. There was thus a vascular ring around the esophagus and trachea, formed by the aortic arch behind, the ductus arteriosus on the left, and by the pul-

monary artery in front. In addition, the left common carotid artery apparently compressed the anterior surface of the trachea to some degree. The autopsy findings strongly suggested that the baby might have been relieved by division of the ductus and also by severance of the left common carotid artery (or as an alternative, the carotid artery could have been moved forward and anchored to the back of the sternum).

DOUBLE AORTIC ARCH

Double aortic arch is a rare abnormality in which the ascending aorta splits into two limbs—which encompass the esophagus and trachea, or only the trachea—and then join to form the descending aorta. In normal development, only the left fourth branchial arch persists to form the definitive arterial system according to Congdon. If the right and left branches both remain, a double arch is established. (A bifid aortic arch is the normal arrangement in reptiles.) Such abnormalities in man may be divided into two groups, the first being less common than the second:

A. Partially obliterated double aortic arch. One limb—usually the anterior (left) one—is represented only by a vestigial remnant or cord. The other trunk is patent and functional.

B. Completely patent double aortic arch. Both limbs are open and each carries some blood to the descending aorta (Fig. 4a). The two trunks may be of the same size but they are apt to be unequal. Lockhart studied one specimen in which the right and left arches were equal in caliber—a very rare finding. Blincoe *et al.* collected 12 cases of double aortic arch, in 9 of which the sizes of the respective branches were noted as follows: in 3 cases, the left arch was 15 per cent smaller than the right; in 3 cases, the left arch was 50 per cent smaller than the right; and in 3 cases, the left arch was quite small, but was still patent. The division of the aortic arch into two channels implies that these surround some mediastinal structures. Malacarne, Sagorski, and Welch described enclosure of the trachea alone, but in all other observations both the esophagus and trachea have been encircled.

It is evident that the confinement of the esophagus and trachea between the two limbs

of a split aortic arch has the potentialities for interference with function of these two tubes. Whether or not symptoms develop depends entirely upon the amount of available room which exists between the two vessels. If sufficient space is present there will be little or no compression of the esophagus and trachea—and the individual can live to an advanced age without symptoms, as is exemplified by the patient of Curnow and others. If, however, the space between the aortic limbs is small, the esophagus and trachea can both be constricted so that serious complaints—or even fatality—result therefrom. If complications appear, they are apt to very do so in early life, usually in infancy. Wolman made an excellent study of 7 cases—all infants under 8 months of age—in each of which there was dysphagia and stridor beginning in the neonatal period, and in each there was death from a pulmonary infection. To these patients with symptoms can be added our 2, both of whom were treated surgically. The first of these has been reported elsewhere (13), the second is included herewith as Case 2.

Wolman has very well described the clinical picture which is presented by these infants, and our experiences closely corroborate his observations. Dysphagia and especially stridor occur shortly after birth and persist. These may be mild or they may be severe and continue until death supervenes or surgical relief is instituted. The respirations are noisy and wheezing; they may even have a crowing quality. Suprasternal and intercostal retraction is common. The child is subject to spells of harsh, nonproductive coughing. The cry is hoarse. The respiratory rate is often elevated. During the act of deglutition, stridor is accentuated and cyanosis sometimes appears. Feedings require much time and patience, since swallowing is delayed and the baby must rest at frequent intervals to improve the breathing. The nourishment and general development may be reasonably good, but these patients are quite subject to superimposed respiratory infections. It is this latter factor which accounts for most of the fatalities. Presumably, the tracheal compression—and possibly the spill-over from

Fig. 4. a, left, Double aortic arch. The ascending aorta divides into two limbs which subsequently join and form the descending aorta. The esophagus and trachea are compressed (Case 2). b, Method of surgical treatment which was employed. The ligamentum arteriosum has been divided to allow the pulmonary artery to fall forward. The anterior (left) limb of the double arch has been severed between the origins of the left common carotid artery and the left subclavian artery. The left common carotid artery is then tacked to the back of the sternum to keep it off the trachea. I.A., innominate artery; L.A., ligamentum arteriosum; L.C.C.A., left common carotid artery; L.S.A., left subclavian artery; S., sternum.

the esophagus—initiate repeated bouts of tracheobronchitis and pneumonia.

Fortunately, the diagnosis of this condition can be readily made during life by roentgenologic means. We are indebted to Dr. E. B. D. Neuhauser for detection of the anomaly in our 2 patients while they were still in a reasonably satisfactory physical condition and could be brought to operative treatment. If the condition is suspected, a swallow of barium and appropriate observations in the lateral and anterior-posterior views will quickly indicate whether there is a compression defect on the posterior esophageal wall. If this is found, films of appropriate density will outline the trachea (because of its air content) and any narrowing can be observed. If the trachea cannot be seen by this simple method, instillation of lipiodol or the use of a lipiodol spray will permit its visualization.

Surgical therapy for this abnormality does not appear to be very difficult. The posterior (right) aortic limb cannot be removed from behind the esophagus, since it is usually the larger of the two channels. However, by dividing some part of the anterior (left) limb, the vascular ring can be broken, the pressure on the trachea can be diminished, and the esophagus can be allowed to displace forward

to some degree. In our first case (13) this was the only procedure which was carried out. It provided a marked alleviation of respiratory difficulties, but it did not abolish them. The residual symptoms were thought to be due to the stretching of the left common carotid artery across the upper part of the trachea like a bowstring. To obviate this factor in our second case, the anterior aortic limb was divided (Fig. 4b) and then the left common carotid artery was held forward (off the trachea) by tacking it to the back of the sternum with a few stitches. This additional step has proved to be worth while because the baby has been completely relieved. (In some cases it might be possible to divide the anterior limb between its source and the origin of the left common carotid artery, and in this way the left common carotid artery would be made to lie alongside the trachea instead of stretching across in front of it. Such a division was not done in our two cases because the distal part of this limb seemed to be too small to supply adequately the left subclavian artery and the left common carotid artery. In short, the size of the various parts of the limb must determine where it will be cut.)

CASE 2. C.A.G., a 5 month old baby, entered the hospital in June, 1945, because of stridor, cough,

fever, and respiratory infection of 2 weeks' duration. The child was cyanotic and in marked distress. The breathing was noisy and rapid; there was marked intercostal retraction. She was placed in a steam room and was given oxygen, penicillin, and sulfadiazine. For 2 days her condition was critical enough to require various stimulants, but following this she gradually improved and was discharged on the 19th day.

Following hospitalization, the baby was in fair condition for several weeks and then again developed a cough and noisy respirations, but was afebrile. Because of progressive anorexia and weight loss, hospitalization was again advised in August. Auscultation revealed rhonchi over both lung fields. The breathing was noisy and stertorous. Roentgenographic studies showed indentation of the esophagus from behind (at the level of the 3rd dorsal vertebra) and an anterior compression of the trachea at the same level.

At operation, an anterior exposure through the left pleural cavity permitted dissection of the superior mediastinum so that the arrangement of the vessels could be accurately ascertained (Fig. 4a). Because of the size of various portions of the anterior (left) limb of the double arch, it seemed best to divide it between the origins of the left subclavian artery and the left common carotid artery. This latter vessel then seemed to stretch across the anterior surface of the trachea at a higher level, and to avoid all such pressure the artery was now lifted off of the trachea and held forward by suturing its adventitia with several silk stitches to the periosteum on the back of the sternum. During the first part of the operation the child's respiratory movements were labored, greatly accentuated, irregular, and noisy—a fact which greatly enhanced the anesthetist's difficulties. However, when the indicated operative steps were completed, the respirations were quiet and entirely normal. The left lung was re-expanded and the chest was closed.

Following operation the residual respiratory infection rapidly responded to treatment and the child was discharged on the 12th day. Since that time the baby has been normal in every way. She swallows without hesitation and has had no stridor or other respiratory symptoms at any time. There has been a rapid gain in weight and the parents are delighted with the operative result.

ANOMALOUS RIGHT SUBCLAVIAN ARTERY

One of the commonest anomalies of the aortic arch is that in which the right subclavian artery arises from the left side of the arch and then courses upward and to the right to reach its normal exit from the thoracic cage (Fig. 5a). This artery may run behind the esophagus, between the esophagus and trachea, or in front of the trachea. Holzapfel made an extensive study of this anomaly and

found the artery to lie: behind the esophagus in 107 cases, between the esophagus and trachea in 20 cases, in front of the trachea in 6 cases. The vessel usually crosses the midline of the body at the level of the third dorsal vertebra. Holzapfel and others have commented upon the frequency with which an aneurysmal dilatation is found in the first part of the artery—just as it comes off the aortic arch. The appearance of a subclavian abnormality is reported to range from 4 cases per thousand dissections (Quain) to 16 per thousand postmortem examinations (Goldbloom). Holzapfel attributes the first authentic case report to Hunauld in 1735. In 1794 Bayford made a precise and fascinating description of a woman who was known to have marked difficulty in swallowing for many years and who at autopsy was proved to have esophageal compression from this malformation. It was he who gave the name of *dysphagia lusoria* to this condition—meaning thereby that the dysphagia was due to a *lusus naturae* (a trick or deception of nature).

This anomalous vessel may not give rise to any symptoms—indeed it does not do so in the vast majority of cases. It has been frequently described as an incidental finding in dissection room subjects, or in postmortem examinations of elderly individuals who apparently did not have any alteration of esophageal function. More recently, it has been noticed in an incidental way during roentgenologic examinations of the alimentary tract. It is possible, however, for the vessel to press upon the esophagus and to disturb the swallowing mechanism. In Kirby's patient a swallowed bone stuck in the esophagus where the vessel crossed it; a perforation of the subclavian artery led to fatal hemorrhage. The 3 year old patient of Vellock *et al.* died in acute respiratory distress because food had become lodged in the esophagus at this point. In our experience this abnormality has been identified in 6 patients by the roentgenologist. In 4 of these children there seemed to be no important difficulty in swallowing. In the fifth there was sufficient hesitancy in deglutition to bring the child to the hospital but this was spontaneously re-

Fig. 5. a, left, Anomalous right subclavian artery, which arises from the left side of the aortic arch and presses on the posterior wall of the esophagus (Case 3) b, Method of surgical treatment for the dysphagia. The subclavian artery has been divided and esophageal pressure thereby relieved. R.S.A., right subclavian artery.

lieved during a few months' observation. In the sixth case there was persistent dysphagia which finally led to surgical exploration for its relief (Case 3 below). This abnormality is not necessarily one which will give its maximum symptoms in early life; there are observations to indicate that the dysphagia may first become manifest, or may be aggravated, in later years when the regional blood vessels become more rigid or become more dilated and thereby press more firmly on the esophagus.

It is now clear that the roentgenologists, by barium visualization of the esophagus, can detect this abnormality with great accuracy. Furthermore, it has been shown that it is possible completely to abolish dysphagia by severing the artery and removing it from behind the esophagus (16). A similar procedure could be carried out when the artery passes between the trachea and esophagus. In short, it is probable that this surgical procedure can be employed for a considerable number of persons who have difficulties—which might not endanger their life—but which are nevertheless quite disagreeable. We do not know of any descriptions of individuals with respiratory distress from a subclavian vessel which passes in front of the trachea. In the event of such an occurrence, division of the artery should be beneficial.

Fortunately, it is possible to divide the first portion of a subclavian artery without serious

impairment of blood flow to the arm. This is true because of the collateral vessels which communicate with the second and third portions of the artery and with the axillary artery. Interruption of the subclavian artery in its first portion will lead to a reduced blood pressure and a diminished flow in the extremity, but the remaining circulation is adequate to supply all of the important demands of the limb.

CASE 3¹. J.R., a 4 month old infant, apparently had marked distress or pain while drinking his milk. This trouble began at about 1 month of age and had increased in severity since that time. The child would be quite hungry, would suck a little, and then would "straighten out with pain." After subsidence of this distress, a resumption of feeding would again bring on fretfulness and crying. There was occasional regurgitation of milk, but no projectile vomiting. At times the baby would take a full feeding, but usually it had to be limited to an ounce or two. It had become necessary to give the baby 15 to 20 small feedings per day to keep up the fluid and caloric requirements. The mother had to spend a major portion of her time in maintaining this schedule. The general physical examination was negative. The radial pulses were equal. Barium examination of the esophagus by Dr. E.H.D. Neuhauser showed a filling defect on the posterior wall of the esophagus which he believed to be characteristic of an anomalous right subclavian artery.

Under cyclopropane anesthesia, the superior mediastinum was explored through a left, transpleural, anterior wound. After a rather easy dissection, an arrangement of vessels was found as

¹ This case has been described elsewhere (16).

indicated in Figure 5a. The right subclavian artery was freed from its retroesophageal bed, the dissection being kept away from the thoracic duct. The vessel was then doubly ligated and divided. Its distal end was allowed to retract to the patient's right—beyond the esophagus (Fig. 5b). The chest was closed after re-expanding the left lung.

Following operation, the color and temperature of the two arms were always equal. Immediately after operation no right radial pulsation could be felt, but there was a faint beat in the right axillary artery. The right radial pulse could be felt on the fifth day. Since that time it has persisted but has been faint. Since operation there has been no hesitancy in swallowing. The child has been placed on a four hourly feeding regimen which is quite satisfactory. The baby was discharged on the tenth postoperative day. Since hospitalization there has been no evidence of dysphagia. Repeat barium examination of the esophagus shows it to be entirely normal.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a shunt between the aorta and pulmonary artery. This by-pass is essential during fetal life, but after birth it normally becomes obliterated and forms the ligamentum arteriosum. If the vessel should remain open the health or longevity of the individual might not be impaired, but such is not the case in most instances. The persistence of this shunt carries certain definite hazards: First, so much blood may be diverted from the peripheral circulation that the physical development is retarded. Second, the large amount of blood which is forced through this arteriovenous type of communication greatly increases the work of the heart and may lead to varying degrees of cardiac embarrassment or failure. Third, the abnormality may become a focus of infection, especially with the *Streptococcus viridans* organisms. The first hazard is one which will be manifest in childhood, the second and third complications rarely appear before adult life. While some individuals with an open ductus may have a reasonable span of life and little or no complications from it, there is ample evidence to show that in a series of patients the life expectancy is only a little more than half of normal.

In most cases a patent ductus arteriosus can be readily recognized. In infancy the physical findings may be confusing and in later life the presence of cardiac failure may

alter the picture somewhat. Except for these circumstances, the diagnosis can be made with great accuracy. There is no cyanosis, clubbing, or polycythemia. The murmur is one which should be rarely confused with the sounds of other cardiovascular defects. It is continuous, has a systolic accentuation, and usually has a rumbling or "machinery" quality. It is loudest in the second or third interspace to the left of the sternum, but it may be transmitted widely in whole or in part. In some instances, it is accompanied by a thrill, which is likewise maximal in the pulmonary area. There are certain features which are absent if the shunt is a small one, but are present if the leak is a large one. These are excessive forcefulness of the heart beat, a lowered diastolic blood pressure, and an increased amplitude of cardiac contraction by roentgenologic observation. The electrocardiograms commonly are normal; they never indicate a right axis preponderance, but occasionally they show some left axis deviation. In general, a patent ductus arteriosus can be recognized (or excluded) by a few minutes of intelligent use of a stethoscope. Laboratory and roentgenologic data may give confirmatory evidence and may be helpful in ruling out other lesions, but too much reliance should not be placed on these accessory aids if the auscultatory findings are not typical of an open ductus.

The indications for surgery are being broadened as more experience is gained with the operative treatment of this condition and as the mortality rate is being lowered to a reasonable figure. For the child or adolescent individual who has retardation of physical growth, closure of the shunt has had a profound effect in augmenting the peripheral blood flow and increasing the subsequent growth and weight of the patient. When there is cardiac embarrassment or failure, stoppage of the ductus leak greatly diminishes the work of the heart and provides a satisfactory cardiac reserve. In the presence of superimposed *Streptococcus viridans* infection, surgical closure of the ductus in 10 patients¹ was

¹None of these patients had responded satisfactorily to sulfonamide therapy before operation, but these drugs were continued for variable periods after operation. In no case was penicillin given either before or after operation.

Fig. 6. a, left, Patent ductus arteriosus, forming a shunt between the aorta and pulmonary artery. b, Currently employed method of closure of the shunt. The ductus is completely divided, so that the pulmonary and aortic ends can be individually sutured. P.A., pulmonary artery; P.D.A., patent ductus arteriosus.

followed by no beneficial effects in 3 cases and by complete cure in the other 7. The technical difficulties of operation are considerable if the patient is beyond 20 to 25 years of age and especially so if there is superimposed cardiac failure or infection. For this reason we are convinced that it is advisable to undertake these operations in childhood before the regional vessels have developed a sclerosis which makes the bandling of them hazardous. In a series of 130 treated patients, varying in age from 11 months to 47 years, there has been a surgical mortality in 5 instances—a fatality rate of 3.8 per cent. Excluding the adults of the series, there have been 90 operations with but one death—a rate of 1.1 per cent. Since the risks of operation have been kept at this low figure in the childhood group, it appears to be a sound policy to advise closure of the ductus in all young individuals, with the hope of avoiding serious complications in later life.

The method of closure of the ductus merits some discussion. Obviously, ligation of the vessel is the simplest procedure but it has drawbacks which are inherent in ligation of any vessel "in continuity." In a high percentage of cases, particularly in young patients and for the smaller shunts, simple ligation is quite satisfactory; but occasionally it gives a disappointing result. In 43 of our cases ligation was employed. In about 80 per cent of these the result was perfect, in about 10 per cent the ligature partially

cut through and some fistula was re-established, in about 10 per cent the ligature was not tied tightly enough to close off all of the shunt. This experience has led to development and adoption of a technique for complete division of the ductus which has now been carried out in 87 instances. The technique which is currently employed is essentially that, with only slight modifications, which has been previously described (15). In these 87 cases there have been 2 surgical fatalities. The first occurred on the operating table; the patient was a 26 year old woman who had been in cardiac failure and who succumbed shortly after the ductus had been divided and its ends closed. The second death occurred 2 weeks after operation from a staphylococcus mediastinitis. Experience with this operation makes it obvious that all of the shunt is completely shut off and that there is no chance for its re-establishment. While the technique may be difficult, the results obtained are so superior that we have completely abandoned the former operation of ligation.

CASE 4. D. E., a 14 year old boy, had some dyspnea on exertion but had never had frank signs of cardiac failure. He had had several prolonged periods when bed rest was advised. A heart murmur was known to be present since infancy. The boy was well developed and nourished. Blood pressure in the right arm was 116 systolic and 60 diastolic. There was a loud, machinery-like murmur, continuous but with systolic accentuation, which was most prominent in the pulmonary area. A promi-

nent systolic thrill was felt in the pulmonary region. Roentgenographic examination showed the transverse diameter of the heart to be slightly more than half of the internal diameter of the chest. The enlargement was particularly in the left ventricle. There was an increased amplitude of pulsation of the left border of the heart. There was an engorgement of the hilar vessels of the lungs. Electrocardiographic tracings were normal.

Operation was undertaken with cyclopropane anesthesia. The ductus was 7 to 8 millimeters in diameter and about 5 millimeters long. Four narrow clamps were applied to it and the vessel was severed between the two middle clamps. The proximal clamp on the pulmonary end was removed to provide a cuff which could be sutured with a running, fine silk stitch. The aortic end was likewise closed. The remaining hemostatic clamps were removed. The chest was closed and the lung was fully expanded.

There were no postoperative complications. The murmur has completely disappeared. The boy was discharged from the hospital on the 11th postoperative day. In the 6 months following operation, he grew 2 inches and gained 15 pounds. He developed an interest in sports and has no limitation of activities.

COARCTATION OF THE AORTA

Coarctation is a narrowing or complete occlusion of the aortic pathway. It has been found in the abdominal and in the lower thoracic portions of the aorta but in the vast majority of instances it is located in the distal segment of the aortic arch or in the uppermost part of the descending aorta, at or near the ductus arteriosus or its obliterated remnant, the ligamentum arteriosum. It has been stated to appear about once in 1500 routine autopsies. Two general forms have been described. In the *infantile* type there is a diffuse narrowing or obliteration of the distal part of the aortic arch so that there is an insufficient supply of blood to the left subclavian artery and possibly to the left common carotid artery. It is usually incompatible with life for more than a short period. In the *adult* type the narrowing is limited to a short segment and appears *beyond* the origin of the left subclavian artery so that it involves that part of the aorta which is joined to the ligamentum arteriosum (or the ductus arteriosus). The separation of cases into these two groups has no sound basis, since the underlying pathological or degenerative processes are probably the same in both. However, the

division does emphasize the fact that the "infantile" type is more extensive, is more prone to be associated with severe cardiac malformations, and leads to fatality in the first months of life, whereas the "adult" type is less apt to be associated with marked cardiac derangements and is compatible with a much longer existence.

The adult type of coarctation carries a variable prognosis. A small number of these individuals have attained old age and have had relatively little incapacitation, but the majority of subjects have developed serious or even fatal complications. The aorta may rupture because of the increased strain which is placed upon it and because of the sclerosis which can appear at an early age. An aneurysm, of a localized or a dissecting variety, may originate near the obstruction. The vascular abnormality may become the seat of superimposed infection, particularly with the *Streptococcus viridans* organisms. Finally, the blood pressure in the upper part of the body usually becomes elevated as a compensatory mechanism. It is not entirely clear whether this hypertension is a direct result of a mechanical blockage in the arterial pathway, or whether it rises from a diminished (or non-pulsating) blood flow to the kidneys. Elevated pressures may be tolerated for long periods of time, but it is obvious that they account for many fatalities on the basis of cardiac failure or central nervous system hemorrhage. Elevations in arterial pressure in the upper part of the body do not bear a direct relationship to the degree of aortic obstruction. The serious nature of coarctation of the aorta is indicated by Blackford's (2) study of 196 cases coming to autopsy; more than 40 per cent of these patients had died between the ages of 16 and 30 years of age.

Any intensive study of the problem leaves little doubt regarding the hazards which must be faced by most individuals who possess a coarctation of the aorta. It is therefore clear that surgical relief is highly desirable for these individuals—provided this can be obtained with a reasonably low mortality rate. Three general surgical approaches can be considered. First, an extensive sympathectomy will diminish the hypertension to

some extent, but how long these beneficial effects will last is still problematical. Second, the aortic obstruction can be by-passed by severing the left subclavian artery at the base of the neck and turning it downward so that it can be anastomosed to the aorta below the obstruction. Blalock and Park have suggested this method, after experimentation on animals, but its efficiency in man is doubtful because severance of the artery would cut off many important channels which invariably come from this vessel. Third, the obstruction may be removed from the aorta and the aortic continuity re-established by anastomosis of its free ends. The feasibility of such a procedure was demonstrated by the experimental work of Gross and Hufnagel (19). It was first performed in humans by Crafoord and it has been further established as a sound surgical procedure by our operative experience in 5 patients.

Coarctation of the aorta can be recognized by quite simple means, the important factor being the detection of an abnormal relationship in the pressures of the arms and legs. Normally, the systolic blood pressure is 20 to 40 millimeters of mercury higher in the legs than in the arms. Pressures of equal magnitudes in the arms and legs are suggestive of a mild aortic block, and lower pressures in the legs certainly indicate an important degree of obstruction in the aorta. Indeed, in most cases of coarctation the pressure in the legs is greatly reduced, and usually cannot be obtained at all with the sphygmomanometer. Palpation over the femoral and other major arteries of the legs shows a marked diminution in pulsation or a complete absence of arterial beats. Hypertension of variable degree may or may not exist in the arms. In children, the pressure in the arms may be relatively normal, but in older patients there is commonly a moderate or marked elevation of pressure in the upper part of the body. If collateral arterial channels have become well developed, and if the individual is not too fat, abnormal pulsations can be seen or felt over these accessory pathways, particularly along the intercostal arteries, over the axillary vessels, and in the regions medial and inferior to the scapulae. Murmurs are extremely variable,

and may be quite misleading. Undoubtedly, marked narrowing of the aorta produces a systolic murmur which can be heard over the left upper portion of the precordium and over the back, particularly to the left of the spine. But if the aortic block is complete there may be no murmur at all. Furthermore, the picture is often confused by the presence of associated cardiac defects such as a bicuspid aortic valve, an interventricular septal defect, or a patent ductus arteriosus, which give rise to audible sounds. Furthermore, large and tortuous collateral channels can initiate systolic or even continuous murmurs. It is therefore evident that a murmur *per se*, cannot be relied upon as an important criterion in making the diagnosis of coarctation of the aorta. Roentgenologic findings are such that they are a valuable aid in recognition of the vascular abnormality.

At first glance, direct surgical measures for excision of a constricted portion of the aorta would seem to be fraught with excessive dangers, yet this has not proved to be true in the limited experience which has been accumulated to date. The experimental findings of several observers have shown that in normal dogs the temporary obstruction (by clamping) of the upper thoracic aorta during operation will be followed in many instances by spinal cord degeneration and serious paralysis of the hind limbs. These observations should not be any deterrent to operation in human beings who have a coarctation of the aorta; under these circumstances there is little or no flow of blood through this segment of the aorta, the collateral channels are well developed, and the aorta can be clamped with impunity because this step will not materially diminish the supply of blood to the spinal cord during the period of aortic clamping. Hemorrhage from the aortic suture line might appear to be an insuperable problem, but this was not so in either of Crafoord's 2 cases, nor in any of our 5 patients. It is well to emphasize that the performance of an extremely accurate and careful anastomosis of the aortic ends completely eliminates the possibility of bleeding at the junction. Thrombosis at the site of anastomosis deserves some consideration, but in no instance has there been any evidence of

Fig. 7 a, left, Coarctation of the aorta, with a high degree of constriction and obstruction, just beyond the origin of the left subclavian artery b, Method of treatment, by excision of the narrowed segment and end-to-end suture of the aorta. Insert shows excised portion—possessing a very tiny lumen.

postoperative blockage of the aorta. Presumably, the establishment of an intima-to-intima anastomosis, combined with the rapid flow through the upper aorta serves to prevent any clotting in this region. It has not been necessary to give these patients anticoagulants during the postoperative period.

One pitfall which has appeared in these operations has been the marked readjustments which must be made in the circulation when the aortic anastomosis has been completed and the clamps are removed from the vessel. By this step, an enormous vascular bed is opened up in the lower part of the body, and the heart may not be able to cope with this strain if it is imposed upon it too quickly. In our first case, it led to an immediate fatality, but in all subsequent cases the clamp was taken off *slowly* (over a 5 to 10 minute period) and the adjustments were thus made in the cardiovascular apparatus in a very satisfactory manner.

The details of operative technique will not be discussed here. They have been presented fully elsewhere (17, 18, 19).

Postoperative studies on our 4 successful cases, and on the 2 which were reported by Crafoord and Nylin, show that there is a very satisfactory appearance of arterial pulsations in the legs and a concomitant fall of the pressure in the arms. The diminution of pressure in the upper part of the body does not take place abruptly—it occurs gradually during

the ensuing 10 days to 2 weeks. Presumably, the peripheral vascular bed (in the lower part of the body) is small before operation and a period of time is necessary to dilate it and thereby provide a large enough system to receive blood and relieve the congestion in the upper part of the body.

CASE 5. J.S., a 10 year old girl, complained of epistaxis of $2\frac{1}{4}$ years' duration. The bleeding was sometimes copious. There were occasional headaches. Slight dyspnea appeared after light exercise. The child was well developed. The heart was slightly enlarged. There was a grade 2 systolic murmur to the left of the sternum, this could be heard with less intensity over the back. Blood pressures were: right arm, 152 systolic, 80 diastolic; left arm, 170 systolic, 110 diastolic. Legs, no beats heard. No pulsations could be felt over the femoral artery or other arteries of the legs. By roentgenographic examination the heart was somewhat full, but of a normal contour. Several ribs were notched along their inferior borders.

Operation was performed under cyclopropane anesthesia. Exposure was made through the left pleural cavity, posteriorly. A marked degree of aortic obstruction was found (Fig. 7a). A segment of aorta, about 6 centimeters long was mobilized, by dividing the ligamentum arteriosum, two bronchial arteries, and two sets of intercostal arteries. The narrowed portion of the aorta was removed, and the ends of the aorta were anastomosed by a continuous stitch which everted the ends (Fig. 7b). The excised specimen had a lumen which was narrowed to 2 millimeters in diameter.

The postoperative course was uncomplicated except for accumulation of fluid in the left pleural cavity which required one aspiration. Postoperatively, good pulsations can be felt in the legs, and

blood pressures are easily obtainable in the legs. The pressure in the arms gradually diminished over a 10 day period. Hospital discharge occurred on the 17th postoperative day. Blood pressures 1 month after operation were: right arm, 120 systolic, 80 diastolic. Right leg 150 systolic, 90 diastolic.

SUMMARY

A brief résumé is made of the more common abnormalities of the aortic arch and the large arteries which arise from it. Many of the anomalies do not give important symptoms, but others have considerable significance since they: (1) give rise to pressure on the esophagus and trachea; (2) impose a burden on the heart because of an arteriovenous type of shunt; or (3) lead to severe derangements in the circulation because of an obstruction in the aortic pathway.

In the first group of malformations under consideration, the esophagus or trachea (or both) are impinged upon by: (1) a right-sided aortic arch; (2) a double aortic arch; (3) a constricting ring of vessels (or remnants thereof); or (4) by an anomalous right subclavian artery. A right-sided aortic arch cannot be changed by surgical means, but if this abnormally placed structure is attached by a ligamentum arteriosum (or a patent ductus arteriosus) to the pulmonary artery so that this latter vessel is pulled back against the trachea or the left side of the esophagus—then division of the ligament (or the ductus) should give some relief. When a double (or split) aortic arch gives respiratory distress, the patient can be greatly helped by cutting the anterior (left) limb. When dysphagia lusoria occurs from a right subclavian artery (which originates from the left side of the aortic arch), the symptoms can be abolished by dividing the artery so that it no longer presses on the esophagus.

Humans with a patent ductus arteriosus are subject to certain hazards, particularly in mid-life. The shunt can greatly increase the work of the heart and lead to varying degrees of embarrassment or failure. Furthermore, the open ductus is frequently the seat of superimposed bacterial infection. While some individuals live a long and active life with a patent ductus arteriosus—particularly if it is a small one—statistics indicate that the

average length of life is little more than half of the normal expectancy. Surgical closure of the ductus has been shown to have very beneficial effects on the cardiovascular apparatus. While surgery can be deferred until symptoms have developed, the technical difficulties of operation at such times is considerable. In contrast, the closure of a ductus at an early age can be accomplished with a negligible risk, and hence we recommend operation in childhood or young adult life before complications have developed. A widening experience in this field makes us feel that ligation of a ductus is usually satisfactory, but that complete division of the vessel is a much superior procedure because it insures complete interruption of the shunt and precludes any possibility of its re-establishment.

Individuals with a high degree of obstruction in the distal part of the aortic arch or in the first part of the descending aorta may live to advanced ages with little or no difficulty, but most of them develop serious or even fatal complications in mid-life. Outstanding among the sequelae of coarctation of the aorta is hypertension which usually appears in the upper part of the body. With this increased pressure may come all of the disorders and dangers of the hypertensive state. Experimental observations show that a section of the upper thoracic aorta can be excised and that the open ends of the aorta can be satisfactorily joined. Such a procedure has been adapted to humans; a narrowed (or completely obstructed) segment of the aorta can be removed and the remaining ends of the aorta can be anastomosed. After performance of this operation, the hypertension is quickly relieved.

THROMBOPHLEBITIS OF THE DEEP VEINS IN THROMBOANGIITIS OBLITERANS

JACOB W. KAHN, M.D., Captain, M.C., A.U.S.

IN spite of the fact that thromboangiitis obliterans is known to involve the peripheral great veins as well as the arteries, no cases of this condition have previously come to my attention in which deep thrombophlebitis was the outstanding clinical manifestation. This disease involves the arteries and veins segmentally in adjacent areas. Perivascular infiltration, progressing to fibrosis, later envelops the artery, vein, and accompanying nerve. Except for the occurrence of superficial migratory phlebitis, the clinical manifestation is most frequently one of arterial insufficiency, rather than that of venous obstruction. Homans says, "So far as the veins are concerned, thrombosis is coextensive with that in the arteries. Actually, venous thrombosis is entirely overshadowed by the arterial disease, and so solidly fixed that embolism never occurs. . . . From a clinical point of view, it is only the arterial disease which is of consequence." Collens states, "Deep venous thrombosis will occur, especially with extensive gangrene, but may be unrecognized until amputation is performed; it can then be seen at the site of amputation."

At this hospital 164 patients with thromboangiitis obliterans have been studied. Many of these soldiers were admitted with bizarre and atypical histories, and the diagnosis was established only after investigation of the vascular system. The following case reports of 2 soldiers whose first manifestations of this disease were in the nature of deep thrombophlebitis are examples. The onset was afebrile with no previous history of acute infection or trauma.

CASE 1. This 36 year old soldier of Polish (non-Jewish) parentage gave a history of fatigue and intermittent claudication of the calves of both legs, of insidious onset, for 10 years. He had had mild dyspnea on exertion and intermittent swelling of the left ankle for the previous 2 years. On October 13,

1943, while overseas, without history of injury or antecedent acute illness, he suffered the onset of pain in the left calf and thigh accompanied by swelling from the toes to the lower thigh. There was no chill nor elevation of temperature. He was put to bed with elevation of the limb and given sulfadiazine for 8 days. On November 6 he was permitted to hang the leg over the side of the bed and 5 days later was allowed to be up. Because of precordial pain, electrocardiograms were made on 3 successive weeks. These showed evidence pointing to myocardial infarction. Because of persistent swelling of the left lower extremity, he was again put to bed. With rest the swelling subsided. The patient was thought to have had thrombophlebitis of the left lower leg.

On January 7, 1944, the right lower extremity suddenly became painful and edematous. Roentgenograms were made for evidence of intra-abdominal tumor which was suspected as the cause of the spread of deep phlebitis from the left to the right lower extremity. These were normal. On February 7, 1944, while being studied under the fluoroscope, the patient suffered a sudden, severe pain in the left chest and later coughed up bright red blood. Roentgenograms the following day showed evidence of pulmonary infarction of the right lower lobe. He was put to bed for 3 weeks and when subjectively improved, was moved to the United States.

Upon arrival he was found to have excessive edema of both lower extremities from the toes to the inguinal regions. The heart and lungs were normal. On March 4, 1944, electrocardiograms again showed evidence pointing to an old myocardial infarct of the anterior wall of the heart. The following day bilateral common femoral vein ligation was performed under local anesthesia and segments of these veins were removed for study. Microscopic examination showed pronounced thickening of the walls, marked perivascular infiltration and occlusion of the lumina by organized thrombi. These thrombi contained only a few slit-like channels lined by endothelium, and containing blood. There was slight infiltration of the walls by small round cells and mononuclear leucocytes. Venograms showed the venous return of the left lower extremity to be by way of the lateral circumflex iliac vein. Following healing of the operative wounds, the patient was encouraged to walk about and was transferred to this hospital for further study and treatment on April 22, 1945.

On examination both lower extremities showed massive pitting edema from the toes to the groins (Fig. 1). During dependency there was rubor of both plantar surfaces and toes. There was no pallor on elevation and both feet were normal in color in the

Fig. 1. Case 1. Massive pitting edema from toes to groins of both lower extremities.

horizontal position. There were no trophic changes and no sweating. The dorsalis pedis and posterior tibial pulses were feeble on the left and absent on the right side. The left popliteal pulse was normal, the right feeble. The radial and brachial pulses were equal and normal. Dorsiflexion of the foot (Homan's sign) was negative bilaterally. The dorsal surface of both feet were warm but both plantar surfaces and toes were excessively cold to touch.

VASOMOTOR TEST

	Oscillometry,			
	Control		After spinal	
	Right	Left	Right	Left
Popliteal	2 0-100 mm	5 0-100 mm	2 5-90 mm	5 0-100 mm.
Tibial	2 0-100 mm	2 5-100 mm	2 5-90 mm	4 0-90 mm
Foot	0 25-90 mm	0 5-90 mm	0 5-70 mm	2 5-80 mm
Skin Temperatures—Degrees F.				
1st toe	84	84	88	91
2nd toe	83	83 5	85	91
3rd toe	82	83 5	89	91
4th toe	82	83 5	89	91
5th toe	82 5	83 5	89	90 5
Plantar	84 5	85	90	91
Dorsum	87 5	87 5	90	90
Ankle	87	87 5	89 5	90
Midleg	89	89	89 5	90
Knee	86	87	87 5	90
Thigh	87	88	88 5	90

Room temperature, 78°F.

Fig. 2. Case 1. Skin surface temperatures in degrees Fahrenheit. See Table I.

Oscillometric readings were normal at all levels of the left lower extremity except for slight diminution in the foot. The readings of the right side showed a marked diminution at the popliteal, tibial, and foot levels in contrast to the corresponding levels of the opposite side. Circumferences of both lower extremities were symmetrically increased. Skin surface temperatures corresponding to the sites illustrated (Fig. 2) of both lower extremities were symmetrically and pathologically diminished in the toes and plantar surfaces of the feet.

Under spinal anesthesia, readings of skin surface temperature and oscillometry were done after complete motor and sensory anesthesia of both lower extremities was present. Similar readings were done, as controls, prior to the spinal anesthesia. The findings are recorded in Table I. These readings showed no increase in oscillometry with only a moderate rise in temperature on the right side but, on the left side, the oscillometry was normal under anesthesia and the skin surface temperatures reached 91 degrees F. This test showed the typical asymmetry usually found with advance organic vascular disease accompanied by secondary vasospasm. The involvement was confined to the right side. The left side was believed to be functional since the vasospasm was completely relieved during anesthesia. A diagnosis of thromboangiitis obliterans was made on the following findings.

1. Evidence of myocardial infarct in a 36 year old patient.
2. Intermittent claudication in both calves of 10 years' duration.

Fig. 3. Case 2. Skin surface temperatures in degrees Fahrenheit. See Table II.

3. Thrombophlebitis of the deep veins of both lower extremities without history of antecedent infection, trauma, or fever.

4. Microscopic changes in segments of excised vein suggestive of thromboangiitis obliterans.

5. Asymmetry of oscillometric readings in both lower extremities despite symmetrical pattern of venous involvement.

6. Rubor on dependency of the toes and plantar surfaces of the feet. These color changes do not accompany the passive congestion of edema in the absence of arterial obstruction.

CASE 2. This 28 year old white soldier of Italian parentage gave a history of fatigue and increasing coldness of both feet and legs of 1 year's duration. The onset was insidious and the symptoms progressive. The feet were cold even in warm weather and frequently kept him awake during the night. He did very little walking because he was employed as a truck driver in the Army. No history of intermittent claudication was given. On March 12, 1944, he experienced sudden pain of knife-like character in the right calf when walking. This pain subsided promptly with rest of the limb. A few days later the right foot and leg became swollen and there was tenderness and pain in the right popliteal region and calf. He reported to a hospital and was treated by rest and elevation of the limb. A diagnosis of thrombophlebitis of the right popliteal vein was made. The pitting edema and the tenderness gradually subsided with rest in bed. During his stay at this hospital a hot water bottle was applied to right calf. Because of anesthesia of the limb the patient sustained a severe burn which was followed by an in-

Fig. 4. Case 2. Pitting edema from right toes to mid-thigh. Deep gangrenous ulcer 9 centimeters long and 5 centimeters wide on anteromedial aspect of right midleg.

dolent, necrotic ulcer of the medial aspect of right leg. He was transferred to this hospital June 15, 1944.

On examination pitting edema was present from the right toes to the mid thigh. A deep gangrenous ulcer 9 centimeters long and 5 centimeters wide was present on the anteromedial aspect of the right midleg (Fig. 4). Dorsiflexion of the right foot (Homans' sign) was positive. Both feet were warm to touch.

TABLE II.—CASE 2. SPINAL ANESTHESIA
VASOMOTOR TEST

	Oscillometry			
	Control		After spinal	
	Right	Left	Right	Left
Popliteal	0.5-90 mm.	2.75-100 mm.	0.75-90 mm.	3.0-90 mm.
Tibial	Flicker	1.5-100 mm.	0.15-90 mm.	2.5-90 mm.
Foot	0	0.15-100 mm.	Flicker	0.5-90 mm.

Skin Temperatures—Degrees F.				
1st toe	77	79	85	91
2nd toe	77	78.5	85.5	90
3rd toe	77.5	78	87	90
4th toe	77	79	85	90
5th toe	78	79	90	91
Plantar	82	83	90	90.5
Dorsum	82	83	86	90
Ankle	85	84	88	89

Knee	87.5	87	89.5	89
Thigh	90	89.5	91	90

Room temperature, 78° F.

On dependency the dorsal and plantar surfaces of the left foot were cyanotic and the toes were ruborous. The right foot was ruborous from the midfoot to the toes. On elevation cadaveric pallor was observed on plantar surface of the right foot and toes. The left side was normal. The dorsalis pedis, posterior tibial, and popliteal pulses on the right side were absent. The left dorsalis pedis and posterior tibial pulses were feeble and the popliteal pulse was weak. Oscillometric readings on the right side were barely perceptible at the tibial and popliteal levels and zero at the foot. The readings on the left side were diminished at the popliteal level, tibial level and the foot. The skin surface temperatures were within normal limits on both sides but 2 to 3 degrees F. higher in the left toes than the right (Fig. 3). Comparative circumferences showed the right leg and ankle to be greater than the left.

Under spinal anesthesia, readings of skin surface temperature and oscillometry were done, after complete motor and sensory anesthesia was present. Control readings were recorded prior to the spinal injection. The findings are recorded in Table II. The test showed advanced obliterative vascular disease of the right femoral artery. The left side showed early obliterative arterial disease in the foot. Severe secondary vasospasm was found on both sides. These findings support a diagnosis of thromboangiitis obliterans involving the major arteries of right lower extremity and distal arteries of left foot.

On the basis of the criteria necessary for a diagnosis of thromboangiitis obliterans, this disease was established in the 2 cases reported. The importance of these case reports lies not in establishing a diagnosis of thromboangiitis obliterans alone, but also in recording the cardinal symptoms which brought about the hospitalization of these patients. Both patients gave a history of insidious and progressive arterial incapacity going over a period of time prior to the onset of the signs and symptoms which precipitated their hospitalization. In neither instance was the incapacity severe enough to excuse them from military service. However, the appearance of spontaneous, afebrile, deep thrombophlebitis without apparent systemic disease, infection, or trauma brought about their hospitalization.

In the first case, the patient suffered arterial involvement not only of his right lower extremity but also of his myocardium. The latter was evidenced by electrocardiographic changes. The deep thrombophlebitis was the factor that led to his hospitalization. The occurrence of pulmonary infarction, secondary to thrombophlebitis, caused by thromboan-

giitis obliterans, is rare, and therefore, is reported in this paper. Biopsy of the veins confirmed the diagnosis.

In the second case, the patient's peripheral vascular symptoms were obscure until involvement of the right femoral vein with clinical manifestations of deep thrombophlebitis appeared. Anesthesia in the skin of the right leg was severe enough to cause a third degree burn by a hot water bottle followed by secondary indolent ulcer. This is not uncommon in the ischemic limb. His treatment, at time of admission to hospital and thereafter, was chiefly concerned with the deep thrombophlebitis.

The diagnosis of thromboangiitis obliterans was made on the basis of the findings of diminished and asymmetrical oscillometric readings in the lower extremities; the presence of dependent rubor, and plantar pallor on elevation; absent unilateral pulses in the feet, and diminished skin temperatures. The persistence of abnormal oscillometry with increase of skin surface temperature in the feet after relaxation of the sympathetic nerves under spinal anesthesia implies the presence of organic vascular disease.

SUMMARY AND CONCLUSIONS

1. The signs and symptoms of deep thrombophlebitis may be present as a clinical symptom in thromboangiitis obliterans.
2. Pulmonary infarction may result from thrombosis of the great veins involved in the process.
3. Every case of afebrile idiopathic deep thrombophlebitis in a young patient must be considered a possible instance of thromboangiitis obliterans and the arterial tree carefully investigated for further vascular involvement.
4. The presence of passive congestion in a limb secondary to venous obstruction may cause a reactive hyperemia which temporarily may mask some of the signs and symptoms of arterial insufficiency.

RELATIVE SURGICAL CURABILITY OF CERTAIN GROSS TYPES OF GASTRIC CARCINOMA

RUDOLF SCHINDLER, M.D., Los Angeles, California

A STUDY of the general statistics presented in 239 cases of gastric carcinoma is the basis of this paper. The paper does not discuss the general curability of gastric carcinoma but deals solely with the relative curability of certain types of this disease.

The most beautiful synopsis of all aspects of the prognosis of gastric carcinoma is found in the admirable book of Livingstone and Pack. The analysis of their enormous material is profound and cannot be successfully attacked. It may be doubted, however, whether all conclusions arrived at by the authors are equally valid. I refer especially to two conclusions. The first one is the statement: "Gastric surgery does not now, nor is it likely in the future, to prove a satisfactory answer for more than the smallest number of patients." This statement is undoubtedly correct for the present time, but it is possible that better conditions may be hoped for in the future. Attempts at mass examinations of symptom free people have been made. Attempts also have been made to discover early and to observe precancerous conditions; the initial research possibly may not be too successful, but there is no reason to lose courage and to discontinue such attempts.

The second conclusion of Livingstone and Pack, the validity of which seems questionable, is the recommendation of resection in as many cases of gastric cancers as possible. This recommendation is given in spite of the pessimistic attitude mentioned. The patient with gastric carcinoma is lost if resection is not performed. Resection alone provides hope. Certainly, it is unjustifiable not to attack surgically the neoplasm in any patient who may be saved. However, in the long run, the recommendation of more and more indiscriminate resections is scarcely the best way to obtain

better results. The authors may have overlooked the fact that large numbers of resections will not only increase the number of surgical successes—cures—but will increase even more the number of surgical failures; as stated before, only a very small number of patients can be cured, so the number of surgical failures will grow overwhelmingly. These failures will discourage the laity, with the result that instead of early surgery being done more often, less and later surgery will be performed—a development to be prevented under any circumstance. Therefore, it is imperative to find ways by which, in a given case, a reasonable prognosis can be made before operation.

It is well known that the degree of malignancy in gastric carcinomas, as in other carcinomas, varies. Attempts have been made to express, by means of the microscopic grading of these tumors, the degree of malignancy and the surgical prognosis. Grading, by microscope, however, is not too reliable. It is true that grades 1 and 2 gastric carcinomas give a much better prognosis than do grades 3 and 4 tumors (3); but grades 3 and 4 carcinomas can be cured with rather great relative frequency. On the other hand, a certain number of grades 1 and 2 tumors prove to be very malignant clinically. Furthermore, microscopic grading cannot be accomplished before operation. Gastroscopic biopsy alone would make such grading possible. While this procedure at present does not yield satisfactory results, it may be developed later. Even then, the finding of a grade 3 or 4 carcinoma would not justify abandonment of surgery.

Another and perhaps better way would be to base the prognosis and the therapeutic procedure on *gross types* of gastric carcinoma. Borrmann has described 4 gross types; it was not his intention, however, to correlate the gross type with the prognosis. The classification presented is based only on gross appearance of the tumor (Schindler, 6; Bockus).

Fig. 1. Carcinoma, type I. Resected specimen. A polypoid tumor protrudes into the lumen of the stomach. The tumor is sharply limited everywhere. Its edge is partly mushroom-like and overhanging. In this case its surface is ulcerated but ulceration is not the rule in type I carcinoma.

THE GROSS TYPES

Type I in this classification is the sharply limited polypoid tumor which projects hemispherically into the lumen of the stomach. It often looks like a mushroom with overhanging edges, its surface presenting numerous nodes and nodules which usually are of different sizes. Ulceration of the surface develops late. The mucosa surrounding this type of tumor is often thoroughly atrophic. Its incidence is about 2.9 per cent of all gastric carcinomas.

Type II is a sharply limited tumor also. It consists of an ulcer surrounded by an elevated wall. This wall has a steep slope toward the surrounding mucosa and is sharply demarcated all around. The floor sometimes shows necrotic material of various colors. The wall may be smooth, or more frequently it is nodular and contains shallow erosions. Its dark red color then is in marked contrast to the pale color of the surrounding mucosa. Its incidence is 17.6 per cent.

Type III is easily confused with type II. It also consists of an ulceration and of a wall. But the wall does not surround the whole circumference of the ulcer. The ulcer, sharply limited on one side, blends diffusely at some point with the neighboring mucosa which is diffusely infiltrated. Therefore, this is not a sharply limited but an infiltrative type of carcinoma. Its incidence is 16.3 per cent.

Type IV comprises the diffusely infiltrative tumors. No sharp limit is found anywhere; sometimes the entire stomach may be infiltrated. Within this infiltration ulceration may develop shallow or deep ulcers. The incidence of this type is 63.2 per cent.

It seems that a tumor of a given type never changes from this type however large it may become. A type II carcinoma remains sharply limited even if it finally involves the entire stomach; a type IV carcinoma is diffusely infiltrative when it is only a few millimeters in diameter. Still more remarkable is the fact that the microscopic structure of tumors of the same gross type may vary markedly. It might be expected that the microscopic structure would determine the gross growth, but this is not so. The sharply limited types I and II may be adenocarcinoma, colloid carcinoma, or medullary carcinoma, microscopically. The infiltrative types often are medullary or scirrhous carcinomas, but they may be colloid carcinomas or differentiated adenocarcinomas as well. What then causes the different types? The answer is not known. There are obviously two possible explanations: (1) that there are features of the microscopic structure responsible for the gross growth which we do not yet recognize; (2) that not the tumor itself, but the reaction of the surrounding tissue is responsible for the gross development of the tumor.

Early in my experience it seemed to me (6) that the prognosis in the sharply limited types I and II differed from that in the infiltrative types III and IV. In order to substantiate this belief care was taken to type as many as possible of the available cases of carcinoma, especially when resection had been carried out. Specimens obtained by resection of tissue usually make reliable typing possible. However, in a number of cases, pathological material could not be obtained, and the gastroscopic or x-ray evidence as to the type involved was not considered to be sufficiently accurate. Such cases were registered as "type not known."

From the previously mentioned incidence it will be seen that statistically the sharply limited types I and II constitute approximately 20 per cent of all cases of gastric car-

Fig. 2. Carcinoma, type II. Resected specimen. The tumor is rather small. A large ulcer is surrounded by a broad wall which is sharply limited at all points. There is no trace of infiltration. In some cases the wall may be thinner; it may even be partly absent. Characteristic is the sharp limitation of the lesion.

Fig. 3. Carcinoma, type III. Resected specimen. At the lower margin of the ulcer there is a very flat wall. In the right upper quadrant the carcinoma invades the gastric mucosa diffusely and the ulcer floor blends imperceptibly with the surroundings. In other cases the wall is much higher and better defined. Yet, if there is any infiltration instead of sharp limitation the tumor must be classified as type III.

cinoma; that the infiltrative types III and IV constitute 80 per cent of all cases. If the prognoses in these forms were approximately

equal, this ratio of 20:80 or 1:4 might well be expected to be found at any stage of the observation.

Fig. 4. Carcinoma, type IV. Postmortem specimen. There is diffuse infiltration along the lesser curvature with ulcer formation. Nowhere is any kind of limitation apparent.

ANALYSIS OF 107 RESECTED CASES

A total of 239 gastric carcinomas was analyzed. Surgery was done in 167, but only in 107 was resection for cure carried out (palliative resections are not contained in this figure). The data in these 107 resections form the basis of comparison of the types of gastric carcinoma.

Of 107 gastric carcinomas resected the gross type was not given in 20 but was known in 87 (see Table I). Eight belonged to type I, 22 to type II, 20 to type III, and 37 to type IV. In 40 cases the course was unknown; either no follow-up was possible or the follow-up did not last long enough. Thus there remain 67 cases, of which the course was known. Five belonged to type I, 12 to type II, 14 to type III, and 25 to type IV; but in 11 cases the type was unknown. In these 67 cases the follow-up was sufficient. But only the 56 cases with known types contribute to the final results of this study. Twenty-five of the 67 died postoperatively, and of these none belonged to type I, 5 to type II, 5 to type III, and 12 to type IV; in 3 the type was unknown. If again the unknown types are omitted, then there were 34 survivors of gastric resection with known course and known type: 5 belonged to type I, 7 to type II, 9 to type III, and 13 to type IV. (In Table I, one may also

find the "possible cures," which are obtained when the postoperative deaths are subtracted from the total number of resections.)

Table I also contains the statistics on surgical failures: those cases in which the death was actually observed and those cases in which recurrence was observed clinically and which usually were seen in the last stage of the disease. It will be noted that in all 8 cases of "unknown type" in which the course was known the patients succumbed; but one of them died from pneumonia, and as there was no autopsy it cannot be stated whether or not there was recurrence. The other 7 patients, however, died from recurrence. Of the 5 type I carcinomas, 2 died before the end of the 3d year. One of them died from heart disease after 2 years, 3 months; autopsy was performed and failed to reveal any sign of recurrence. The other type I case had had a polyposis *en nappe* (at gastroscopy 26 "single" adenocarcinomas were counted) and one of the polyps close to the cardia had developed into a sharply limited type I ulcerated carcinoma. The surgeon, believing that he was dealing with a benign tumor, made only a local excision. Half a year later the patient developed a carcinoma of the upper esophagus and succumbed quickly. Only 4 weeks before the death a successful gastroscopy was carried

TABLE I.—DISTRIBUTION OF GROSS TYPES IN 107 CASES OF RESECTED GASTRIC CARCINOMA

Gastric resections	Types				Unknown	Total
	I	II	III	IV		
Total cases	8	22	20	37	20	107
Course unknown	3	10	6	12	9	40
Course known	5	12	14	25	11	67
Postoperative deaths	0	5	5	12	3	25
Possible cures	8	17	15	25	17	82
Follow up in postoperative survivors	5	7	9	13	8	42
Failures { Death observed	2*	2*	3	6	6†	19
{ Recurrence observed	0	2	6	6	2	16
3 year survivors†	(3)	(4)	(1)	(1)	(0)	
3 year cures	3	3	0	1	0	7
5 year cures	2	2	0	0	0	4

†The cases of 3 year cures are contained in line showing 3 year survivors, also; 2 of the survivors are found also among the recurrences.

*One patient died from heart disease—autopsy showed no recurrence. One patient died from carcinoma of the upper esophagus.

†One patient died from coronary occlusion, 1/4 years postoperatively; at autopsy no recurrence found.

†One patient died from pneumonia.

All other patients died from recurrence of the carcinoma.

out (in spite of the obstructing esophageal tumor), and no sign of recurrence was seen. No permission for autopsy could be obtained.

Of the 7 type II cases followed, 2 patients died before the end of the 3d year and in 2 others recurrence was observed. One of them lived longer than 3 years, however; this was a 3 year survivor, but not a 3 year cure. In 1 of the 2 cases in which the death was observed patient died from coronary occlusion after 2 years and 4 months. An autopsy was performed and no recurrence was present.

Of the 9 type III cases followed, all had recurrences of the carcinoma. One of them was a 3 year survivor. There was no observed cure.

In 6 of the type IV cases followed, death from recurrence was observed. In 6 others, the presence of recurrence was stated clinically. But 1 patient survived. He was seen alive and apparently healthy 3 years, 4 months after the operation.

If then we are to compare the types of the 7 remaining 3 year cures, we find that 3 of them belonged to type I, 3 to type II, none to type III, and 1 to type IV. If we combine the types I and II to the group of sharply limited carcinomas and types III and IV to the group of infiltrative tumors, then we should expect, as shown previously, that the ratio would be 1:4, if both groups would have equal chances

for cure. Instead, we find a ratio of 6:1. A patient having a sharply limited type of gastric carcinoma had a 24 times greater chance for a 3 year cure than a patient having an infiltrative type of tumor so far as these data are concerned.

Only 4 cures of 5 years' duration were known in this sampling of data but it is noticeable that all 4 of them belonged to the sharply limited group (type I–II), none to the infiltrative group!

In Table II attempt has been made to express the results obtained by percentage figures. Again, it should be borne in mind that an incidence ratio of 1:4 between the sharply limited and the infiltrative forms should be expected. The distribution of types in 87 cases of gastric resection in which the type was determined was as follows: 34.5 per cent of all cases belonged to types I–II, 65.5 per cent to types III–IV. The ratio, instead of the expected 1:4, is 1:1.9. Sharply limited tumors would appear to be resectable almost twice as often as the infiltrative tumors.

The ratio of postoperative deaths to the number of resections for the different types is also given in Table II; the postoperative mortality is 16.7 per cent for types I–II, but 29.8 per cent for types III–IV. Here a death ratio of 1:1 would be expected on the assumption of equal postoperative mortality. In

TABLE II.—PERCENTILE DISTRIBUTION OF GROSS TYPES OF GASTRIC CARCINOMA

	Type I	Type II	Type III	Type IV
Distribution of types in 87 cases in which the type was determined	8 = 9.2% 30	22 = 25.3% 34 5%	20 = 23% 57	37 = 42.5% 65 3%
Postoperative deaths	0 = 0% 5	5 = 11.7% 26.7%	5 = 15% 17	11 = 30.8% 29 8%
Known 3 year cures of all originally typed cases	3 = 37.5% (of 8) (of 30)	3 = 13.6% (of 22) 20%	0 = 0% (of 10) (of 57)	1 = 1% (of 37) 1.8%
1 year cures of all typed patients with known course	3 = 60% (of 5) (of 17)	3 = 15% (of 13) 35.3%	0 = 0% (of 14) (of 39)	1 = 4% (of 13) 2.6%
3 year cures of followed-up postoperative survivors	3 = 60% (of 5) (of 12)	3 = 45% (of 7) 50%	0 = 0% (of 0) (of 11)	1 = 17% (of 12) 4.5%
5 year cures of followed-up postoperative survivors	3 = 40% (of 3) (of 12)	3 = 28.6% (of 7) 33.3%	0	0

stead we find the ratio to be 1:1.78. The relative postoperative mortality of the infiltrative types is 1.78 times higher than that of the sharply limited types.

Earlier in this paper, when the absolute figures were discussed, it was stated that the ratio of types I-II 3 year cures to types III-IV 3 year cures was found to be 6:1 instead of the expected 1:4. But for statistical purposes such a simple comparison seems scarcely permissible. The relation between the types at different stages of the observation varies, and it is perhaps fairer and more logical to relate the 3 year cures to the number of each type observed at the various stages. This attempt has been made in Table II. We may compare the 3 year survivors with all originally typed cases. There were originally 30 cases of types I and II and 57 cases of types III and IV. But of the 30 types I and II cases, 6 had a 3 year cure representing 20 per cent. Of the 57 types III and IV cases only 1, or 1.8 per cent, was a 3 year cure. These percentages 20:1.8 equal 11:1. Thus of all originally typed resected cases, a type I-II patient had an eleven times greater chance for a 3 year cure than did a type III-IV patient. It must be recalled that these ratios are based on relatively small samplings. The problem of the reliability of the findings is discussed in a statistical note appended to this paper.

We may choose to relate the final known 3 year cures to all typed patients with known

course (Table II). Here the postoperative mortality is included, and since it is higher in types III and IV than in types I and II, the results become still more unfavorable for the infiltrative types. In 17 type I-II patients and in 39 type III-IV patients the course was known. The 3 year cures in types I-II (6) constitute 35.3 per cent; those in types III-IV (1), only 2.6 per cent. The ratio is 13.5:1. Analyzing all typed patients with known course we find that types I-II patients have a 13.5 times greater chance of a 3 year cure than have types III-IV patients.

Finally it may be interesting to eliminate the postoperative deaths and to compare the final results with those postoperative survivors who had a sufficient follow-up. Twelve postoperative survivors of types I-II were followed up and 22 postoperative survivors of types III-IV. The 6 types I-II 3 year cures constitute 50 per cent, the one type III-IV 3 year cure constitutes 4.5 per cent of these survivors. The ratio is 11:1. If we analyze only the postoperative survivors, the types I-II patients still seem to have an eleven times greater chance of a 3 year cure than do the types III-IV patients.

Whichever of these comparisons is chosen, it becomes apparent that a patient having a sharply limited gastric carcinoma has a 10 to 13 times greater chance of a 3 year cure when resection is performed than has a patient with an infiltrative carcinoma.

I hope that the startling results may be a stimulus for the continuation of similar research. In my opinion, even single cases of long term cures are interesting, if the gross type can be stated beyond doubt. And we certainly are looking anxiously for the publication of 5 year cures in infiltrative forms of gastric carcinoma. Although 3 year apparent cures by no means prove a real cure (Nathanson and Welch), even the publication of several cases of 3 year cures in infiltrative forms would seem worthwhile because they would contrast sharply with the one case from these data.

It is not my impression that the average life duration of the patient with an infiltrative carcinoma is shorter than that of a patient with a sharply limited form, if no operation is performed. I have no statistical material to prove this point. Not rarely patients with diffusely infiltrative carcinomas are seen who live relatively long, about 3 years, not uncomfortably. On the other hand, sharply limited tumors, especially of type II, may be seen to grow rapidly and terminate the life of their bearers in a few months. All conclusions one wishes to draw from the materials presented can possibly refer only to the surgical prognosis.

If the results obtained here should prove correct in 10 years, then they would influence the treatment of gastric carcinoma greatly. Then obviously one should try to diagnose the favorable limited types of gastric carcinoma as early as possible, and one may become reluctant to attack infiltrative forms surgically unless the respective tumor is very small.

At present it is much too early to draw any conclusions; but the question may come up: how can we recognize the different types without exploratory laparotomy? Whichever method we may use we will be careful never to make the diagnosis of an unfavorable infiltrative type as long as there is still the remote possibility of a favorable limited type. However, by x-ray examinations diffuse infiltration can often be stated without ambiguity, and a wall surrounding the entire lesion sharply will often permit the diagnosis of a type II carcinoma. Relief technique is indispensable for such diagnoses (8). Often then the Car-

man meniscus sign will be found which is almost pathognomonic for the favorable type II, and only rarely will be seen in the unfavorable type III.

Gastroscoopically the types can be recognized often beautifully. Great care, however, should be exercised. The gastroscopist must not dare to diagnose the type, if he has not seen the entire circumference of the tumor. Schindler and Letendre (7) published reports of 74 cases in which gastroscopic typing was checked surgically. Three cases were believed to belong to type I; but one of them proved at surgery to be a type II carcinoma. Fifteen cases were believed to belong to type II at gastroscopy. This was correct in 14 cases, but 1 case proved to be an infiltrative type IV carcinoma. In 20 cases, a type III tumor was diagnosed. In 19 cases this diagnosis proved to be correct, but one case was found later to be a favorable type II. In 36 cases a diffusely infiltrative type IV carcinoma was diagnosed, but this diagnosis proved to be incorrect in no less than 7 cases. In 3 cases a type III carcinoma was found in the gross specimen. But in 4 cases a type II carcinoma proved to be present, and this mistake is obviously important. This experience led to the conclusion to be careful with the gastroscopic typing of gastric carcinoma. Generally it can be stated, however, that with combination of x-ray and gastroscopy a rather satisfactory typing of gastric carcinoma is possible before surgery.

SUMMARY

1. In 7 cases of gastric carcinoma a 3 year cure was observed, and in 4 of them a 5 year cure. Of the 7 observed 3 year cures, 6 belonged to the sharply limited gross types (types I-II) and only 1 to the infiltrative types (types III-IV). After 5 years only 4 patients having had a sharply limited carcinoma (types I-II) were known to be alive.

2. These data are too limited to permit any final conclusions, but the results of the analysis should stimulate further research about the incidence of the gross types of gastric carcinoma among the long term postoperative survivors.

3. By combination of x-ray and gastroscopy usually the gross type of a gastric

MANAGEMENT OF PLASTIC MAXILLOFACIAL WOUNDS IN AN EVACUATION HOSPITAL

CHARLES H. LEECH, M.D., F.A.C.S., Major, M.C., A.U.S., Lima, Ohio, BORDEN C. DRUM, D.D.S., Major, D.C., A.U.S., Conover, North Carolina, and H. F. OSTERHAGEN, M.D., Captain, M.C., A.U.S., Traverse City, Michigan

THIS report is based on the case records of 1148 patients treated by a plastic maxillofacial team during approximately one year's work in a 400 bed evacuation hospital where the incidence of plastic maxillofacial injuries was 7.1 per cent. All of these patients, except 79 burn cases, received an anesthetic. Of the patients under consideration, 770 had only maxillofacial wounds but the remainder, or 32.2 per cent, had both maxillofacial and other injuries which were also operated on by the team. A total of 2,350 operative procedures were performed upon the reported group: 1,927 plastic maxillofacial and 423 additional operations.

GENERAL CONSIDERATIONS

On each successive opening of the hospital this team represented the most forward maxillofacial personnel. Therefore more than 90 per cent of the patients were seen within 20 hours after injury. The peak load always occurred during the first few days of each set up. Since immediate treatment was an urgent necessity, it seems worth while to review salient features in the plan used in caring for the injured, preliminary to surgery.

Preliminary care. First, it was found most advantageous for the plastic maxillofacial team to do the triage on patients with plastic maxillofacial injuries. This procedure (1) permitted a continuous flow of patients to the operating table, alternating the severely injured with the less severely injured so that the time necessary for the preparation and anesthetizing of the former could be utilized in the treatment, under local anesthesia, of the latter; (2) established priority of cases for surgery; (3) took cognizance of patients in shock from anoxia and requiring establishment of an open airway before they could become surgical risks; and (4) permitted

recognition of those cases in which pressure dressings did not control hemorrhage.

Second, to eliminate unnecessary handling, patients were sent to x-ray tent, returned to preoperative or shock tent, and later taken to surgery without being removed from their litters. During times of peak load no baths were given before patients reached the operating tent, since exposure in an improperly heated tent would only increase their discomfort and hazard.

Preoperative medication and therapy were administered by preoperative or shock personnel after the patient had been seen by a member of the plastic maxillofacial team. Atropine, grains 1/150 to 1/100, was given to every patient. Morphine was or was not given, depending on the amount administered by forward medical units. As has been pointed out by others, mere lack of signs of morphine effect is no criterion for the administration of more of the drug, since absorption may have been delayed. A patient who is in more or less shock and exposed to the cold may show no signs of morphinism for as long as 9 hours after subcutaneous administration of 1/2 grain of morphine.

Careful attention to the state of the patient determined whether or not blood, plasma, or crystalloid fluids should be used. One death (see Case 1 under "Deaths and Their Causes") can probably be attributed to the lack of such supportive treatment.

Third, in the operating tent we preferred to use a master instrument table with two operating tables, thereby reducing waste in sterile instruments and consequently saving time.

Fourth, we found compelling reasons for using a general anesthetic in the majority of cases. It was impossible to give these patients adequate surgical preparation under local anesthesia, for the wounds were filled with

caked sulfanilamide powder, dirt, and dried blood so that it was necessary to scrub the area with white soap and liberal quantities of water and to irrigate the wounds with sterile saline solution. The high percentage of patients who had multiple injuries requiring surgical treatment presented another objection to the use of local anesthesia.

After the patient was surgically prepared and draped, examination was completed and the findings correlated with the roentgenograms to permit a planned operation.

Surgical care. Careful and adequate débridement was our rule. "Débridement," as used in this paper, comprehends the removal of all devitalized tissue, detached bone, and foreign material, including missiles. Aided by adequate roentgenological localization we were able to remove all foreign bodies in almost every instance. Such removal could be accomplished with greater ease and profit at this stage than at a later operation, because the wounds were already open and exposed to their depths for excision, and the paths of the missiles were still unabridged.

In our hands, primary closure of battle wounds of the face and neck was consistently achieved if operation were performed within 20 hours after injury. Seldom were we confronted with a patient seen too late for the successful performance of primary definitive surgery, other than reconstructive. Since it was a policy to evacuate none except the slightly injured under a minimum of 5 days postoperatively, and since some patients who presented special problems were held as long as 10 days, it is possible to speak with some degree of accuracy regarding the incidence of postoperative infection: superficial or stitch infection occurred in less than 5 per cent of the patients; no cases of cellulitis developed in the reported series.

Primary removal of foreign bodies was responsible, in great measure, for this low incidence of postoperative infection. Observations made here point to the conclusion that nowhere else does careful, adequate, and early débridement pay better dividends than in plastic maxillofacial surgery. In contrast, those who reached the general hospital without receiving definitive treatment at a more

forward installation had, by the time of their admission, such a degree of infection that a prolonged period of treatment was necessary. This resulted in not only an extended period of hospitalization, but, more important, in definite scar formation and contracture as well. It became evident that maxillofacial injuries should receive the benefit of definitive surgery done at the most forward element possible.

WOUNDS TREATED

Soft tissues of the face. It would be difficult to exclude from this discussion the treatment of skeletal injuries to the face, because trauma of the supportive skeletal structure accompanies all except simple lacerations and abrasions in this area. Fractures with displacement need to be reduced and supported. If that can be accomplished, then accompanying injuries of the soft tissues can be treated as if the skeletal structure were undamaged. In many instances repair of the soft tissues gives adequate support to the fracture. When the fracture is reduced and the tissues sutured in their normal relationship an important step in the prevention of infection has been achieved.

Our usual procedure was as follows: The patient was given endotracheal ether with Flagg apparatus. The face was scrubbed with white soap and water and then shaved, though if the eyebrow were involved that area was prepared by clipping so that the normal hairline might serve as a guide in

approximating skin edges. The face was then scrubbed again with white soap and water, dried with sterile towels, and draped. Careful débridement was accomplished. The wound was irrigated with sterile saline solution. Fractures were reduced. If the maxillary sinuses were involved a nasal antrotomy was done, followed by packing with vaseline gauze. Frequently packing served the further purpose of supporting a fractured zygomatic malar. Hemostasis was meticulously effected. The deeper structures were approximated in their normal relationship with interrupted No. 0000 catgut or silk sutures, obviating all dead space. Skin margins were approximated with vertical mattress sutures of nylon or silk.

The question of tissue loss is an interesting one. There is no war wound of the face in which tissue loss is not represented, though it reaches its maximum in the avulsive type of injury. However, the degree of loss nearly always seems greater than it actually is. Often in reconstructing a severely injured face one is surprised to find almost all of the soft tissue present. The defect appears greater because of the distortion.

Blast or tattoo injuries. Multiple foreign bodies, powder, tar, gravel, dirt, and small bits of metal imbedded in the skin and subcutaneous tissues as the result of a nearby explosion of land mine, bomb, or shell were among the tattoo injuries. Surgical care of such injuries was tedious and time consuming. While the patient was under anesthesia, the area was thoroughly scrubbed with a stiff brush, soap and water, and then cleansed with ether as a solvent for tar and grease. All residual particles and fragments were carefully picked out with a curette or the point of an abscess knife.

Enucleations. This plastic maxillofacial team performed 51 enucleations, but only in those cases in which penetrating or perforating wounds of the eye were associated with collapse of the globe, as all other injuries of the eye were cared for by the ophthalmologist. When dealing with a badly mutilated eye we were careful to remove all retinal tissue, to prevent sympathetic ophthalmitis.

Eyelids. Of the 69 injuries to upper and lower eyelids, 17 were of such severity as to require reconstructive surgery. Treatment in the latter group consisted of (1) thorough cleansing of the wound, (2) protection of the cornea, and (3) early evacuation.

The remainder of these injuries were primarily sutured. Wounds that extended through the whole thickness of the lid were closed in two layers. The sutures of the conjunctival layer were brought out in the conjunctival sac and the edges of the cutaneous layer were loosely approximated, the sutures being tied on the surface. Due care was exercised to approximate accurately the borders of the lid.

External ear. We operated on 56 patients who had injuries of the external ear. Of this group 20 represented varying degrees of tissue loss and 2 patients had complete avulsion. Where the loss of tissue was not too great we effected reconstruction and primary closure. We débrided and excised to the point where accurate approximation of the wound margins was possible and then held the margins in place with interrupted nylon sutures supported by folded gauze and pressure dressing. Lacerations extending into the external auditory canal required careful suturing so that healing by granulation and eventual contraction might be avoided. When the loss of tissue was so great as to preclude primary repair we felt it mandatory to cover residual cartilage.

Lips. Of the 59 injuries to the lips which required operation, 15 were defects which could not be closed, including 9 which represented loss of one or both commissures. Where tissue loss occurred, all portions of the wound adjacent to the area of loss were closed, and in the resulting defect mucous membrane was sutured to skin.

Nose. Seventy-seven patients with injury to the soft tissues of the nose were treated. Fourteen of these represented a degree of tissue loss which precluded primary suture. Those injuries which extended through the full thickness of the ala were closed in two layers, due care being used in the approximation of the borders.

Tongue and floor of the mouth. We operated on 43 injuries of the tongue. Nineteen of these involved the floor of the mouth. In treating wounds of this area meticulous débridement and total hemostasis were accomplished. Mucous membrane in the floor of the mouth was carefully closed to prevent contracture. The tongue was closed in layers to obviate all dead space. Wherever there was loss of tongue tissue, débridement and closure were carried out in such a manner that one half of the tongue was not appreciably longer than the other.

Accessory paranasal sinuses. Surgical treatment was given to 171 patients with injury to one or more of the paranasal sinuses. In many instances roentgenological examination revealed the presence of a foreign body in the sinus. This we endeavored to remove whenever possible, believing that its continued presence must certainly result in infection.

We treated 115 injuries to one or both of the maxillary sinuses. In each instance nasal antrotomy was done and vaseline gauze drain installed through the antrotomy opening. It was also necessary to do a Caldwell-Luc operation on 11 of these patients in order to remove foreign bodies.

The anterior wall of the frontal sinus was involved in 16 cases. Treatment consisted of débridement and closure with rubber tissue drain. An effort was always made to preserve the superciliary ridge. If the posterior wall of the frontal sinus were injured the case was referred to the neurosurgeon.

Three injuries which involved both the ethmoidal and sphenoidal sinuses were seen. In one of these patients spinal fluid was draining from the left nares. In that instance the entrance wound was sparingly débrided, loose bone fragments were removed, and the wound of entrance carefully closed. Nasal drainage was adequate. Due to the frequency

with which such injuries involve the meninges, both extensive débridement and search for a foreign body must be avoided.

FRACTURES

Nasal bones. Seventy-six fractures of the nasal bones were reduced. Since the majority of patients in this group had multiple associated injuries which received simultaneous attention, endotracheal anesthesia was preferred. Asch forceps were used to manipulate the bones into realignment. The nasal septum was straightened and an attempt was made to return it to its groove in the vomer, but because of associated fractures this last step was not possible in every instance. Dressing consisted of dental molding compound over gauze, held in position by strapping with adhesive tape. It was necessary in 5 instances to evacuate a collection of blood from the septum. This evacuation was accomplished by means of an incision extending through the mucoperiosteum parallel to the floor of the nose.

Mandible. Of the 136 fractures of the mandible treated, 20 had lost so much bone tissue that continuity of the mandible could not be re-established. It was our policy to remove all primary and secondary foreign bodies, completely detached fragments of bone, loose teeth, and roots which were in the fracture line. Due care was exercised to remove no bone with periosteal or soft tissue attachments.

We found the anatomical classification of fractures useful only occasionally, as descriptive terms are of small benefit when methods of immobilization are being considered. When teeth remained, an all important consideration was immobilization of the mandible with the teeth in normal occlusion. Our method of choice was to attach the adapted half-round nickel silver labial arch bar to each arch separately with No. 18 gauge stainless steel wire, and subsequently to establish elastic intermaxillary traction. The latter was delayed until the postoperative period of nausea was passed.

Fractures associated with bone and tissue loss were supported in the same manner if sufficient teeth remained on both sides to give

adequate stability to the arch and still maintain the proper occlusal relation of the teeth, as well as the proper spacing of the bone fragments. The maintenance of such relationship and spacing we considered of paramount importance, for failure in these respects would unnecessarily complicate reconstructive work at a later date. We found it possible to stabilize adequately even multiple comminuted fractures of the mandible by means of the arch bar and intermaxillary traction, provided a sufficient number of teeth remained.

The edentulous mouth presented a more serious problem. There the fracture was supported by circumferential wiring. This was accomplished by selecting the proper fitting dental tray, adapting softened dental compound to the repositioned mandible, and wiring around the tray in three or more places so that the lower jaw might be firmly secured and immobilized. Again No. 18 gauge stainless steel wire was the ligature of choice.

Only once, and then with an avulsion complete except for the left condyle and ramus, did we find it necessary to use extraoral fixation on the mandible. In that instance we stabilized with fixation from skullcap to

angle and lower border of ramus, with the hope of maintaining a functional left temporomandibular joint for future grafting and prosthesis.

Associated simple fractures of the alveolar process were invariably accompanied by loss of teeth. If the roots were not involved we attempted reduction and splinting, again securing stabilization by fixation to the remaining teeth with the half-round arch bar and stainless steel ligatures.

Dependent drainage was established by rubber tissue drain in all compound comminuted fractures of the mandible.

Maxilla. Ninety-four fractures of the maxilla were treated. In this series multiple associated fractures of the different bones of the face were common. In 13 cases the injuries were such as to cause extensive loss of bone.

Fixation, the type chosen depending upon the nature of the fracture, was of utmost importance both for control of hemorrhage and for maintenance of an adequate airway.

Fractures of the alveolar process alone were treated the same as were those of the mandible. Often we found that the unilateral horizontal fracture could be maintained in place by the use of an arch bar attached to the adjacent normal maxilla and firmly ligated.

The bilateral horizontal fracture of the maxilla presented the most difficult problem because of the downward and backward or the downward and forward displacement. Here again we attached the labial arch bar to the teeth in the maxilla, applied the plaster skullcap, and supported the floating segment of the maxilla with stainless steel wire passed through the soft tissues, over the zygoma, and attached to the arch bar in either of two locations: in downward and forward displacement the area of the first bicuspid was that of choice; in the backward displacement the area of the first molar was preferred.

When lacerations of the commissures of the mouth were present we avoided use of the Kingsley splint and similar appliances, as such devices tended to separate the wound edges and to cause a breakdown of our primary closure.

If both maxilla and mandible were fractured we did not hesitate to use elastic traction along with fixation to a plaster cap. This procedure eliminated the ineffective Barton's bandage, which we felt had no place in plastic maxillofacial surgery in an evacuation hospital.

Zygomatic malar. Fracture of the zygomatic malar was recorded in 93 patients, 19 with severe loss of bone. These fractures were usually associated with other fractures of the facial bones and, except in those cases in which the zygomatic bone alone was injured, the maxillary sinus was also involved. Entrance or exit wounds were invariably adequate for the employment of elevators. These, in conjunction with suitable tenaculum forceps for grasping the bone, were the mechanical aids necessary for reduction. After reduction was accomplished, in many instances accurate apposition and suture of soft tissues furnished adequate stabilization. Packing of the maxillary sinus with vaseline gauze through an antrotomy wound also gave support. In a few cases direct wiring or external traction with a skullcap was necessary.

Mastoid. We operated on 14 patients with compound fracture of the mastoid process. Operation consisted of débridement and removal of the air cells, introduction of sulfanilamide and penicillin powders, closure of the wound, and installation of a vaseline gauze drain.

Multiple associated fractures. One hundred and twenty-eight multiple associated facial fractures were recorded. These included fractures of the palate, ethmoid, vomer, turbinate, and lacrimal bones and will not be discussed individually.

OPERATIONS ON THE NECK

It is unnecessary to comment at length on either superficial or deep wounds of the neck which did not involve vital structures; there were 251 patients in this category. Débridement of the wound, with great care to remove all foreign and devitalized material, was routine in these cases. Whenever possible before final closure of extensive wounds the patient was allowed to cough or strain in order to make certain that hemostasis was complete.

Tracheotomy. Tracheotomy was performed 37 times. All tracheotomies were done under local anesthesia.

The low collar incision was used in preference to the vertical incision described in textbooks. The ribbon muscles were divided in the midline and the third and fourth tracheal rings were identified. A vertical incision was made through those two rings, a small segment of each ring was removed, and the tracheotomy tube was inserted. Bleeding was controlled and the wound was closed with interrupted silk sutures. Requiring tracheotomy were 15 perforating wounds of the larynx, 11 perforating wounds of the pharynx, 7 avulsive wounds of the mandible with severe injury to tongue and floor of mouth, 2 perforating wounds of the trachea, and 2 perforating wounds of both trachea and esophagus.

Wounds of the larynx. Seventeen patients with perforating wounds of the larynx, resulting from penetrating or perforating wounds of the neck, were cared for by our team. Of this series, 15 were operated on. The 2 patients on whom we did not operate require some explanation. One, a German civilian, had received a perforating wound resulting in the loss of the anterior portion of the thyroid cartilage. Through this wound a tracheotomy tube had been inserted at a field hospital. On admission to our installation the patient had pneumonia with a temperature of 103 degrees F. He died 36 hours later. The second patient, an American soldier who was admitted to the hospital with marked emphysema over neck and chest and in a state of severe shock, died a few hours after admission.

Of the 15 operable patients, 12 had perforating wounds of the thyroid cartilage and 3 had perforations of the cricoid. They presented varying degrees of emphysema and respiratory obstruction. Tracheotomy was performed under local anesthesia in all cases. This was followed by exposure of the entrance and exit wounds of the larynx through a collar incision at the level of the wound of entrance. The wound was débrided and hemorrhage was controlled; fragments of the cartilage were repositioned and held in place

by careful suture of the surrounding tissue. The wound was then repaired by primary suture.

Pharynx. Twenty patients with perforations of the pharynx were treated. These wounds were carefully débrided and closed in layers. Since we were very anxious to obtain primary healing of the mucous membrane, a soft rubber tissue drain was placed through the side of the neck only up to the suture line in the mucous membrane. The drain was removed on the second postoperative day. In several instances the entrance or exit wound was posterior to the sternocleidomastoid muscle. These injuries were handled in the same manner, except that the drain was placed in the posterior pharyngeal or lateral space and the wound was closed. All wounds in this series healed by primary intention.

ESOPHAGUS

Four perforating wounds of the cervical esophagus were seen and may be classified as follows:

1. Anteroposterior wound of the neck, perforating larynx and esophagus (Case 1).
2. Anteroposterior wound penetrating trachea and esophagus (Cases 2 and 3).
3. Transverse penetrating wound of the neck (Case 4).

CASE 1. The missile perforated the larynx at the level of the middle cricothyroid ligament, thence through the esophagus, coming to rest in the muscles of the posterior neck.

Tracheotomy was done under local anesthesia. The patient was then given a general anesthetic consisting of pentothal sodium with nitrous oxide and oxygen. The neck was opened with an incision extending from the wound of entrance to the tip of the left mastoid process; this was connected with a vertical incision along the anterior border of the sternocleidomastoid muscle, permitting the development of anterior and posterior flaps. The sternocleidomastoid muscle was divided transversely. The left superior thyroid vessels were identified and divided, permitting the left lobe of the thyroid to be retracted downward and mesially. The cervical portion of the esophagus was mobilized and the entrance and exit wounds were closed by pursestring sutures of silk, reinforced by mattress sutures. A Penrose drain was inserted into the posterior esophageal space and the wound closed. The laryngeal wound was closed by suturing adjacent tissue over it. Foreign body was not removed.

This patient was given nothing by mouth for the first 72 hours. During that time fluid and protein balance and sulfanilamide level were maintained by intravenous injections. After 72 hours the patient was given liquids, and starting on the fifth day he was given a soft diet. The Penrose drain was removed at the end of the first 48 hours; tracheotomy tube and suture were removed at the end of the fifth postoperative day. Primary healing of the wound had resulted. The patient was permitted out of bed on the seventh postoperative day and was evacuated the following day.

CASE 2. This patient presented an anteroposterior wound perforating both the trachea and the esophagus. He was treated in exactly the manner described in Case 1, and made an uneventful recovery.

CASE 3. This man also had an anteroposterior wound which perforated both trachea and esophagus. He died from anoxia resulting from a large blood clot which formed a complete bronchial cast. Had tracheotomy been performed and suction instituted earlier in the chain of evacuation, we believe this patient would have had a better opportunity to live.

CASE 4. A German civilian who was transferred to our hospital after operation in another installation had a transverse wound of the neck which perforated the cervical esophagus. The portal of entry was in the left inferior posterior triangle of the neck; the exit was through the right sternocleidomastoid muscle corresponding to the lower border of the thyroid cartilage. Operation consisted of débridement and carrying the dissection of the exit wound to the posterior esophageal space, leaving the latter open with a light packing to produce an esophageal fistula. Cervical cellulitis and mediastinitis had developed, accompanied by an elevation of temperature ranging from 101 to 104 degrees F. Sulfanilamide and penicillin therapy was instituted, together with supportive treatment with blood and plasma. It was possible to pass a Levin tube for feeding. This patient was evacuated to a civilian hospital, so no follow-up was possible.

In all 4 instances of wounds of the esophagus one symptom was outstanding—painful deglutition. This symptom was far more severe in wounds of the esophagus than in wounds of either the larynx or the pharynx. The presence of such a symptom, together with consideration of the course of the missile, determined the diagnosis.

VASCULAR INJURIES

External carotid. Patients who required ligation of one of the external carotid arteries were those who had received either avulsive wounds of the mandible or serious injuries in

the region of the temperomandibular joint, with division of the internal maxillary artery.

Early in the campaign a patient was brought in 1 hour after being hit by an 80 millimeter shell which produced a severe avulsion of the mandible. Hemorrhage was so severe that tracheotomy had to be performed with patient in the prone position. When we turned the patient over, the amount of macerated tissue made it impossible to determine which side was primarily responsible for the bleeding.

Under local anesthesia the right external carotid artery was exposed and compressed. This failed to control hemorrhage. The left external carotid artery was then exposed and observed to be much smaller in caliber than the right. When the smaller vessel was ligated hemorrhage was promptly controlled. This experience led us to believe that serious injury to one of two terminal branches of the external carotid produces vasospasm of the artery. Recognition of the vessel in spasm may be a useful diagnostic aid in deciding whether the right or the left external carotid artery is accountable for the major portion of the hemorrhage in avulsive injuries of the face.

Lingual artery. Frequently we were able to control hemorrhage from the tongue by suture ligation in the tongue itself. However, we found such treatment ineffective in 5 instances. Those patients required exposure and ligation of the lingual artery in the submaxillary space.

Internal jugular vein. Three patients with division of the internal jugular vein were seen. Whenever the path of a missile suggested injury to the contents of the carotid sheath and a hematoma of the neck was observed, a planned operation was instituted, with adequate exposure of the sheath above and below the injury. Then when the clot was dislodged, accidentally or intentionally, the resultant hemorrhage could be quickly controlled.

Common carotid artery. Two patients with injury to the left common carotid artery were admitted. The first was seen 18 hours after injury. At this time hemiplegia already existed, with marked restlessness, confusion, irritability, and total lack of co-operation. Proximal and distal ends of the vessel were ligated. The patient died on the third post-operative day.

The second patient was admitted 16 hours after injury, and, as with the first patient, hemiplegia had already developed. This patient was not operated on. He died the second day after admission.

ANESTHESIA

Anesthesia for the seriously wounded maxillofacial case is not always ideal in an evacuation hospital, due to sudden waves of patients with resultant shortage of anesthetists and anesthetic equipment. Discussion among surgeon, oral surgeon, and anesthetist almost always leads to the choice of an anesthetic that is satisfactory to all. Two factors make this anesthetic problem different from that in surgery of the trunk or the extremities. First, it may be difficult, if not impossible, to maintain an adequate airway before, during, and after operation. Second, the anesthetist and his paraphernalia must not interfere with the surgeon. In our experience, frequently the former and sometimes both factors necessitated tracheotomy before a general anesthetic was begun; and it was soon determined that the extensively or seriously wounded patient could best be cared for under general anesthesia.

Every patient who received ether was inducted rapidly to avoid the vomiting, straining, and struggling which would almost certainly result in active bleeding. Even so, suction had to be used in most cases, either during induction or just before insertion of the endotracheal tube.

The endotracheal route was generally used in the administration of ether, but whether nasal or oral depended on the nature of the injuries and on the procedure contemplated.

For example, a patient requiring the placing of labial arch bars and other intraoral procedures was handled with the nasal tube. The largest possible tube (up to and including size No. 38 F.) was used to facilitate the passage of a large urethral catheter so that aspiration of the trachea might be accomplished through the same channel. This latter procedure was necessary because many patients had aspirated a large amount of blood and secretion by the time they had been transported from the battlefield and anesthetized. We believe that

routine aspiration was in part responsible for the total absence of postoperative pneumonia in the reported series of cases. Neither were there any demonstrated cases of atelectasis, and only once was it necessary to use the bronchoscope before a patient left the operating table.

To introduce the endotracheal tube a laryngoscope with a flat blade was preferred because the tongue was displaced less by it than by the large half-round type. The laryngoscope was useful not only in passing the tube under direct vision but also in clearing the pharynx of blood, secretion, and the bits of fractured bone or teeth which were often found there. Immediately after the tube was passed, it was connected to the ether can, which will be described later. Then the pharynx was again carefully cleansed under direct vision, and 2 to 4 feet of gauze moistened in warm water or saline solution was lightly packed about the tube, to prevent aspiration of blood and secretion. Neither mineral oil nor vaseline was used because the surgeons objected to the mess of the oil on their hands and instruments. Seventy-five consecutive cases were closely followed post-operatively; no serious pharyngitis or hoarseness was noted.

A modified Flagg can was always used for the administration of endotracheal ether. This simple apparatus consisted of a bent metal adapter to which was attached a thick walled rubber tube, $\frac{1}{2}$ inch inside diameter and 5 to 10 inches long, which led into the ether can. The tube should not be longer than 12 inches at the most, to avoid a large dead air space and its attendant accumulation of carbon

dioxide. The "ether can" was a 14 ounce evaporated milk can with two $\frac{5}{8}$ inch holes in the top. The inspired air was drawn over the $\frac{1}{4}$ to $\frac{1}{2}$ inch of ether in the can and thence through the tube and into the lungs. This sufficed to keep the patient in light surgical anesthesia. If the plane of anesthesia became too light its depth could be increased simply by lowering the tube further in the can, or even by warming and gently agitating the can with the hand. Oxygen was administered, when needed, through a catheter inserted in the open hole of the can.

This method of administering ether was greatly favored by our team. The apparatus was easy to clean, could be covered by drapes, and was almost completely automatic; as the patient became more deeply anesthetized his respiration became more shallow and less ether was vaporized. The hazard of explosion was controlled by having the maxillofacial table situated at the end of the operating tent away from central supply and from stoves, when they were used.

Gas-oxygen-ether could have been used more frequently, but since 8 to 10 operating tables were being used simultaneously, it was felt that the two gas machines could best be used for the abdominal and chest cases. Approximately 50 per cent of the ether patients were inducted with gas-oxygen-ether and then intubated. The tube was then connected to the Flagg can, freeing the gas machine for other uses.

Though it was a rule that no patient whose wounds communicated with any of the air passages, including the paranasal sinuses, should receive pentothal, Table IV reveals a relatively high number of pentothal anesthetics administered. This was possible only because approximately one-half of the wounds in this series did not communicate with air passages.

Intubation under pentothal anesthesia was accomplished in some instances, but the tendency to severe laryngospasm and coughing made such procedure unpopular. Ethel chloride and drop ether, used for induction in about 25 per cent of the patients, were especially reserved for those who had extensive wounds of the mouth, to get them through the

excitement stage quickly and quietly. Patients were merely brought to a state of unconsciousness with ethyl chloride spray; then a fresh mask was applied and the administration of drop ether was begun. One death can probably be attributed to ethyl chloride induction.

Sodium pentothal was frequently used for patients requiring operation on the posterior neck. In such instances it was most convenient, from the anesthetist's point of view, to use the neurosurgeon's occipital headrest. Not only was the airway then easy to maintain but the surgeon also welcomed the resultant stability and adjustability of the patient, who could be settled in a comfortable position while still awake.

Seventy-nine patients received no anesthetic. Nearly all of that group had burns of the hands and face requiring a minimum of painful manipulation. All had received a preoperative injection of $\frac{1}{4}$ to $\frac{1}{2}$ grain of morphine.

POSTOPERATIVE CARE

Postoperative treatment of plastic maxillofacial injuries was guided in part by the length of time the patient was to remain in our installation. The hospital operated under directives declaring chest and abdominal injuries nontransportable for 7 and 10 days, respectively; therefore retention of the severely injured plastic maxillofacial patients did not at any time interfere with its mobility. Since all the latter type patients were operated upon under a general anesthetic which was administered through either an endotracheal catheter or a previously placed tracheotomy tube, scrupulous attention to their postoperative care was required.

Early postoperative care. During the anesthetic and opiate recovery period it was essential to maintain a dry airway, to correct dehydration and shock, and to continue chemotherapy.

It was not necessary to remove the endotracheal catheter immediately after surgery, and leaving it *in situ* conferred two advantages: (1) it facilitated the maintenance of a patent and dry airway, as did use of a tracheotomy tube, and (2) it expedited the administration of oxygen whenever that procedure was necessary.

Immediately available suction for each patient was imperative. The length of the period during which this procedure was required depended in great part on the amount of material aspirated and on the state of shock. Electrically operated mechanical suction was most desirable, but there was not a sufficient number of such units in the hospital. Consequently, that equipment had to be supplemented by foot pedal apparatus, exhaust suction from gasoline motors, water suction, or a simple syringe suction. Only by utilizing one or more of these supplementary means was adequate suction available in postoperative and shock wards.

The parenteral use of crystalloid solutions for the correction of dehydration and the further use of blood and plasma in the treatment of shock were necessary. When blood was used in a preservative solution containing chloride, care was exercised in the further administration of saline solutions so that water retention might be prevented. We found it better to use 5 per cent glucose in distilled water, rather than saline, under those circumstances.

Chemotherapy consisted of penicillin, 20,000 Oxford units every 2 hours by intramuscular injection, and sulfadiazine, 1 gram every 4 hours by mouth. This was routine, unless special circumstances required other means of administration or different dosage. Sodium sulfathiazole in solution was given intravenously to patients unable to take sulfadiazine by mouth.

Late postoperative care. Following the anesthetic and opiate recovery phase, the patients were set upright to facilitate venous drainage and to reduce edema, thus preventing tension on sutures and local anoxia of the involved tissues.

For those patients who had injuries of the oral or pharyngeal cavities, feeding was begun at once by oral or nasal catheter, depending on the nature of the injury. By this means those patients were immediately on a liquid diet containing 2500 to 3000 calories. The No. 18 F. urethral catheter with 50 cubic centimeter syringe was excellent for this purpose. The catheter was removed after each feeding. After two or three lessons the patient could

feed himself. This method not only insured adequate food and fluid intake, but also improved the wound hygiene.

Meticulous hygiene of the cavities was then instituted. This consisted of irrigation with physiological saline solution followed by hydrogen peroxide or potassium permanganate solution. Sinuses or bones exposed by extensive loss of tissue were sprayed with activated zinc peroxide solution. Here again, after two or three lessons, the patient welcomed the opportunity of caring for himself.

When adequate early surgical treatment was carried out it was seldom necessary to allow the tracheotomy tube to remain in place for more than 4 days. Throughout the period covered by this report a high percentage of tracheotomy tubes were removed before the patient was evacuated, and during the last 5 months all tubes were removed before that time. In no case did follow-up records reveal any ill effects. We believe that there is a tendency to allow the tube to remain in place longer than its period of usefulness, thereby prolonging the time required for closure and increasing the amount of scar tissue.

BURNS

Practically all burns seen at this evacuation hospital were second or third degree burns. In approximately 70 per cent of the cases morphine was sufficient for débridement and dressing. The remaining 30 per cent had additional injuries requiring administration of a general anesthetic. Petrol and flash burns of the extremities were treated, following débridement, with the application of fine mesh vaseline gauze, pressure dressing, and immobilization.

Due to gross contamination by excretions from nose and mouth, dressings were not used on the face, except for evacuations. When patients arrived at the ward they were placed in Fowler's position on a sterile sheet with a sterile towel for pillow cover. As a result of maintaining this position less edema developed.

All phosphorus burns admitted to the hospital had received previous application of copper sulfate. Even so, the more deeply imbedded particles required excision, but if this were

unnecessary the burns were treated as petrol or flash burns.

Three civilian children with third degree burns of face and hands were treated with excision, full thickness skin graft to the face, and split thickness grafts to cover the hands. This treatment was adopted because both evacuation to civilian hospitals and later care were very uncertain.

Postoperative treatment of burns entailed (1) administration of blood and blood plasma for hemoconcentration, (2) chemotherapy, and (3) the maintenance of adequate fluid intake.

DEATHS AND THEIR CAUSES

CASE 1. Clinical diagnosis: perforating wound of face, resulting in compound comminuted fracture of the mandible, bilateral horizontal compound comminuted fracture of the maxilla, and extensive lacerations of the face. Cause of death: irreversible shock.

CASE 2. Clinical diagnosis: perforating wound of neck, with perforation of larynx. No operation performed. Cause of death: emphysema with cellulitis.

CASE 3. Clinical diagnosis: perforating wound of the face: portal of entry was in the region of the left temporomandibular joint, and exit was through floor of the mouth. No operation performed. Cause of death: hemorrhage from internal maxillary artery.

CASE 4. Clinical diagnosis: multiple perforating wounds, with third degree burns of both legs. Cause of death: irreversible shock.

CASE 5. Clinical diagnosis: perforating wound of trachea. No operation performed. Cause of death: hemorrhage producing clot which completely filled the tracheobronchial tree.

CASE 6. Clinical diagnosis: perforating wound of neck. No operation performed. Cause of death: induction of anesthesia with ethyl chloride.

CASE 7. Clinical diagnosis: perforating wound of larynx. Not operated on. Cause of death: pneumonia.

CASE 8. Clinical diagnosis: second and third degree burns involving 80 per cent of the body surface. Cause of death: irreversible shock.

CASE 9. Clinical diagnosis: second and third degree burns of 100 per cent of the body surface. Cause of death: irreversible shock.

CASE 10. Clinical diagnosis: perforating wound of neck with division of left common carotid artery. Cause of death: thrombosis of the vessel from the site of injury to the circle of Willis, and with hemiplegia.

CASE 11. Clinical diagnosis: perforating wound of the neck with division of the left common carotid artery. Cause of death: thrombosis of the vessel from the site of injury to the circle of Willis, and with hemiplegia.

SUMMARY AND CONCLUSIONS

1. Two cases with successful primary closure of the cervical esophagus are reported.
2. Endotracheal anesthesia is preferred in the severely injured maxillofacial patient.
3. Low collar incision is preferred for the tracheotomy. Tracheotomy tubes often remain *in situ* longer than their period of usefulness.

4. Vasospasm of the external carotid artery can be used as a diagnostic sign in determining whether the right or the left external carotid artery is responsible for the major portion of the hemorrhage in avulsive types of injury to the face.

5. Primary closure of neck and face wounds is the treatment of choice.

TRANSVERSE PRESENTATION

JOHN TOTTERDALE COLE, M.D., and FORBES DELANY, M.D., New York, New York

A REVIEW of early obstetrical literature reveals that abnormal presentations usually ended with destruction of the fetus. But as obstetrics emerged as an art, with its goal a healthy mother and infant, instruments and methods were devised to cope with the problem of transverse presentation. Internal version, external version, forceps, and cesarean section have reduced the number of unfavorable results. The accumulation and the intelligent interpretation of statistical data have further reduced mortality.

Stephenson reviewed the original paper of Sir Thomas Denman (1785) who superficially described the mechanism involved in 3 cases of neglected transverse presentation in which spontaneous delivery eventually occurred. He ascribed the term spontaneous evolution to this rare outcome. Stephenson also reviewed the original paper of Douglas (1819) who made a more searching inquiry of the phenomenon. Roederer (1756) described *partus con-* *duplicato corpore*, or birth with the doubled body. Eastman again reviewed the subject in 1913. In modern obstetrics this form of delivery is of historical interest and is only rarely seen in the neglected case. Modern teaching insists upon some form of interference when a patient is encountered with a persistent transverse presentation. The physician who pursues a course of watchful waiting in these difficult cases invariably finds himself driven to

desperate and heroic therapy, often resulting in death of the infant and/or the mother.

In the late 1800's an abundance of German literature appeared concerning the treatment of transverse presentation by internal podalic version. Most authors accepted internal podalic version as the treatment of choice, and were chiefly concerned with the state of the cervix at the time such interference was justified. Sachs and Poeck later (1926) summarized the opinions of leading German obstetricians about half of whom felt that internal version should be performed prior to full dilatation, and the other half believed that internal version was not indicated until full dilatation of the cervix had occurred. Cesarean section was not entirely forgotten, but it was thought that the operation was not indicated unless additional factors were present. Kamnicker stated that the mother should realize the added risk, and her wishes should be considered. Chatunrew was of the opinion that cesarean section was indicated in cases in which the membranes ruptured early and that both fetal and maternal mortality should be reduced by such treatment. In the more recent American literature series of cases have been reported by Eastman, Novey and Schneider, and Torpin. Eastman's series covered the period from 1846 to 1931, and Novey and Schneider's series the period from 1920 to 1930. It is the purpose of this paper to present a more recent series of cases, and if possible, to evaluate the influence of advances in surgery, chemotherapy and the development of

Cesarean section was not entirely forgotten, but it was thought that the operation was not indicated unless additional factors were present. Kamniker stated that the mother should realize the added risk, and her wishes should be considered. Chatunzew was of the opinion that cesarean section was indicated in cases in which the membranes ruptured early and that both fetal and maternal mortality should be reduced by such treatment. In the more recent American literature series of cases have been reported by Eastman, Novey and Schneider, and Torpin. Eastman's series covered the period from 1896 to 1931, and Novey and Schneider's series the period from 1920 to 1939. It is the purpose of this paper to present a more recent series of cases, and if possible, to evaluate the influence of advances in surgery, chemotherapy and the development of

From the Department of Obstetrics and Gynecology, Cornell University Medical College, and The New York Hospital.

blood banks, which appear to be influencing the method of treatment in cases of transverse presentation.

In a review of the records of 45,000 deliveries at The Woman's Clinic of The New York Hospital between 1932 and 1946, 78 cases of transverse presentation are recorded. Arbitrarily, all cases of twin deliveries in which the second twin was transverse have been eliminated since in this instance the problem is not the same. Cases in which the original presentation was transverse and spontaneous version occurred have also been eliminated because many such cases were not reported and one could not be certain of the validity of the findings. It was also necessary to eliminate cases in which the fetus weighed under 1500 grams, for here again many were not reported and they apparently offered no special problem. However, it was just as necessary to include the group in which the fetus weighed between 1500 to 2000 grams as will be pointed out later. The authors fully realize that cases in this group went unrecognized or were not reported, and the incidence of transverse presentation in which the fetus is between 1500 to 2000 grams must be greater than indicated in their series. No attempt has been made to differentiate between the so-called oblique presentation and transverse presentation. The broad definition of transverse presentation—where the long axis of the fetus crosses the long axis of the mother—has been used throughout the study (Chart 1).

Chart 1. Etiological factors in 78 cases of transverse presentation.

The importance of the etiological factors lies in its influence on the plan of treatment of each individual case. As in other series of cases it was difficult in a large number of instances to determine the reason for the abnormal fetal presentation. In general, the findings are much the same as those of other investigators. Myoma uteri was considered the etiological factor only in those cases in which the myomas were of such size that they might presumably affect the presentation of the fetus. When there was no other obvious etiological factor, the cause was attributed to multiparity if the woman had previously given birth to two or more infants, to prematurity if the infant weighed under 2500 grams, and to excessive size infant if the infant weighed more than 4000 grams. It is evident that it would be more proper to call these the probable etiological factors. Of unusual interest is the single case of transverse presentation in which the causative factor was the presence of a kidney overlying the pelvic brim as proved at operation. This patient had had one previous pregnancy which was also complicated by a transverse presentation terminated by cesarean section.

TABLE I.—DISTRIBUTION OF 78 CASES OF TRANSVERSE PRESENTATION ACCORDING TO PARITY

Parity	No. cases	Percent
0	17	21.8
1	26	33.3
2	20	25.6
3 or 4	9	11.5
5 or more	6	7.7

Total—78 Total—99.9

Average—1.8

A tabulation of the 78 cases of transverse presentation according to parity again emphasizes the influence of multiparity as an etiological factor (Table I).

TABLE II.—DISTRIBUTION OF 78 CASES OF TRANSVERSE PRESENTATION ACCORDING TO BIRTH WEIGHT OF THE INFANT

Infant weight in grams	No. cases	Percent
1500—2000	2	2.6
2000—2500	14	17.9
2500—3000	13	16.7
3000—3500	25	31.1
3500—4000	17	21.8
4000—4500	7	8.9

Total—78 Total—100.1

Average—3003 grams

A distribution of the patients according to the birth weight of the infant shows the greatest number of cases of transverse presentation occurred when the infant weighed between 3000 and 3500 grams (Table II).

FETAL MORTALITY

The fetal mortality figures reported by the German authors vary widely, being from 19.0 to 47.2 per cent. This appears to be due to the fact that some authors included in their series all cases in which the fetus weighed 1000 grams or more. It is obvious that some clinics were seeing many more neglected cases of transverse presentation than others. Novey and Schneider report the fetal mortality to be 30.7 per cent in 114 full term infants at the University Hospital, Baltimore. Eastman's figure is 47.2 per cent in 93 cases at the Johns Hopkins Hospital when the fetus weighed 2500 grams or over, and 30.0 per cent when he eliminated the cases in which the fetal heart was not heard on admission to the hospital. In the present series, there were 62 cases in which the birth weight of the infant was 2500 grams or more, and 9 fetal deaths occurred (14.5%). If the 4 cases are discarded in which the fetal heart was not heard on admission to the hospital, the fetal mortality was 8.6 per cent (Table III).

TABLE III.—FETAL MORTALITY IN 62 CASES OF TRANSVERSE PRESENTATION IN WHICH THE FETUS WEIGHED 2500 GRAMS OR OVER

Classification	No cases	No deaths	Per cent Mortality
Total cases	62	9	14.5
Fetal heart present	58	5	8.6
Method of delivery			
Vaginal	28	5	18.0
Abdominal	30	0	0.0

In the entire series of 78 cases there were 18 fetal deaths. As will be noted from Table IV, 7 deaths occurred prior to the onset of labor, 8 were associated with labor and delivery, and 3 were neonatal deaths.

These fetal mortality figures are lower than generally reported. We believe that this fact is due to our high incidence of delivery by cesarean section which in turn has been influenced by the development of blood banks and advances in chemotherapy, particularly the introduction of the sulfonamide drugs and

penicillin. There were 5 live-born infants who sustained injuries during delivery (all delivered by internal podalic version and breech extraction): 2 nerve injuries, 1 intracranial hemorrhage, 1 fractured clavicle, and 1 hematoma of the knee.

MATERNAL MORTALITY

In the series there occurred 1 maternal death (1.3%), which rate compares favorably with other reports. Eastman records 5 maternal deaths in his cases and makes the interesting observation that all 5 deaths occurred in immature or premature labors, the largest child weighing 2030 grams.

The patient was a 37 year old, black, septipara, tredecimgravid, with negative Wassermann, and normal pelvis. Her expected date of confinement was June 17, 1940. She was admitted to the hospital at 6:30 p.m. on June 7, 1940, because of the absence of fetal movement for 2 days and the onset of mild labor at 1 p.m. accompanied by slight vaginal spotting. On admission no fetal heart sounds could be heard and the patient had a fever of 38 degrees C. which was attributed to intrapartum infection. Abdominal examination revealed a tender uterus and the fetus in transverse presentation. A sterile vaginal examination at 8 p.m. showed the cervix to be soft and 6 centimeters dilated with the maternal surface of the placenta palpable over the entire cervical os. Brisk vaginal bleeding was present so the placenta was pierced by the examining hand, both feet grasped and pulled into the vagina. This controlled the hemorrhage. Anesthesia was discontinued and with each uterine contraction, gentle traction was made on the feet. Fifty minutes later the patient was delivered without difficulty of a 2740 gram, macerated infant. One minute later the placenta was expressed spontaneously and completely. The cervix was inspected and found to be intact. The uterus was explored and no defect noted. The uterus

contracted well. The total blood loss was 400 cubic centimeters.

Immediately following delivery the patient received 500 cubic centimeters of whole blood intravenously and was in good condition. One and one-half hours later the blood pressure was found to be 60/20 and the patient was exhibiting the classical signs of shock. The uterus was found to be relaxed, and an additional 400 cubic centimeters of blood and clots were expressed from the uterine cavity. It was apparent that the shock was out of proportion to the blood loss, so the patient was prepared for re-examination of the uterine cavity. At 11:15 p.m. the second examination revealed a rent in the lower uterine segment on the right side and extending into the right broad ligament. The patient was prepared for further transfusions and immediate laparotomy.

A hysterectomy was performed in 42 minutes, during which time the patient received 1050 cubic centimeters of whole blood, but her condition remained critical. One hour after operation the patient had reacted and was rational and co-operative. Her general condition had improved. The blood pressure was recorded at 78/40; the pulse of fair quality but rapid. During the next hour her course was steadily downhill in spite of the transfusion of an additional 500 cubic centimeters of whole blood. She did not respond to the usual emergency drugs, and expired 7 hours after delivery (4 hours after hysterectomy).

METHOD OF DELIVERY

It will be noted in Table V that almost half of the deliveries in this series were by cesarean section. In 93 cases of transverse presentation in which the fetus weighed 2500 grams or over and the fetal heart was heard on admission to the hospital, Eastman reports 21 cesarean sections (22.6%). Novey and Schneider record 21 sections in 151 cases (13.9%). In the present series, considering only infants weighing over 2500 grams when the fetal heart was present on admission, there were 58 cases of which 30 were delivered by cesarean section (51.7%).

Table VI describes the methods of treatment and delivery in greater detail.

TABLE VI.—DETAILS OF METHOD OF DELIVERY IN 78 CASES OF TRANSVERSE PRESENTATION

1	External version, abdominal binder, spontaneous delivery
1	External version, manual fixation of head, spontaneous delivery
1	Spontaneous delivery

TREATMENT

In the treatment of transverse presentation no strict regimen can be outlined for all cases. To some extent the treatment of an individual case depends upon certain variable factors.

1. Etiological factor. The presence of a pelvic tumor, contracted pelvis, uterine abnormality, or placenta previa might contraindicate vaginal delivery and make cesarean section mandatory. Conversely, the presence of a premature infant might influence the attending physician to allow delivery from below. But as previously pointed out, Eastman's 5 maternal deaths occurred when the infant weighed 2030 grams or less.

2. Age and relative sterility of the patient. In the elderly primipara with a long history of relative sterility, the importance of the fetus is greater. In such a case one would be inclined to choose cesarean section as the method of delivery. Again, one would surely hesitate to perform a hysterectomy on a neglected young primipara, and would use every means to preserve the organ for future pregnancies.

3. Duration of pregnancy. If confronted with a previable infant, radical measures are to be avoided. Under certain conditions one would be more inclined toward vaginal delivery when the fetus was small, and toward cesarean section when the fetus was excessively large.

4. Condition of fetus. If the fetus is in dire straits, clinically dead, or malformed, delivery from below is usually indicated and cesarean section to be avoided.

5. Duration of labor. When abdominal delivery is decided upon, the duration of labor affects the selection of the type of cesarean section to be performed. As labor becomes protracted, thinning of the lower uterine segment makes external and internal version increasingly hazardous procedures.

6. Condition of the membranes. With rupture of the membranes and the escape of the amniotic fluid, prolapse of the cord is an ever-present and extremely unwelcome complication. External version is more difficult, often impossible, and frequently injudicious. Braxton Hicks or internal podalic version may lead to fetal death unless the patient may be immediately delivered.

Antenatal care. Novey and Schneider emphasize the importance of adequate prenatal care. During the antenatal period careful examination would reveal the presence of a pelvic tumor, contracted pelvis, uterine abnormality, hydramnios, or an excessive size infant. The attending physician would then have some insight as to the cause of a persistent transverse presentation as the patient approached term. If such conditions were overlooked their recognition might prove much more difficult at time of labor. The multipara with a pendulous abdomen or ventral hernia may obtain great relief from an abdominal support during the latter months of pregnancy, and at the same time the likelihood of transverse presentation is reduced. Although most physicians are reluctant to accept external version as a routine procedure as advocated by Ryder, its use in the last few months of pregnancy when a transverse presentation is discovered is of value. If studies during the antenatal course indicate that abdominal delivery will be necessary, the patient may be admitted to the hospital at or near term for elective cesarean section.

Precautions. It has been the policy of the Woman's Clinic of The New York Hospital to take certain precautions when a patient is admitted with the fetus in transverse presentation. Immediate blood typing and matching

is performed in anticipation of a difficult delivery. If the etiological factor is unknown or obscure, a careful search is carried out to determine the presence or absence of pelvic contraction and fetal abnormalities. Soft tissue x-ray films may also be done when placenta previa or pelvic tumors are suspected. A sterile vaginal examination may be performed. Propylactic sulfonamide drugs and/or penicillin may be administered.

Observation. At all times the patient should be under close surveillance for signs of impending uterine rupture. Auscultation of the fetal heart is carried out at frequent intervals so that the first signs of fetal embarrassment will be noted. Constant watch is kept for rupture of the membranes and the prolapse of a small part or the cord.

In discussing the treatment of transverse presentation the methods to be employed seem naturally to fall into groups which are directly dependent on the duration of labor and the condition of the membranes.

Early labor. Membranes intact. It would be interesting to know just how many times spontaneous versions occur. It is probably safe to assume that in one-half or more of cases the fetus rotates spontaneously so that either the vertex or breech presents. External version should be attempted. If it is successful, the presenting part should be fixed manually over the pelvic brim until it is secure; if unsuccessful, the patient is entitled to a short trial of closely observed labor to allow every opportunity for spontaneous version to occur. Although many advocate the use of abdominal binders to maintain the new presentation, we have found spontaneous reversion to the transverse to be common. With an abdominal binder in place auscultation of the fetal heart and abdominal palpation are difficult. Often one is lulled into a sense of false security only to find as labor progresses and the membranes rupture that the cord or a small part is present in the vagina. If absolute indications are present for cesarean section, the patient should be prepared for operation.

Early labor. Membranes ruptured. In this instance the treatment is much as outlined above, but once the membranes are ruptured external version becomes a dangerous pro-

cedure unless the cervical os is tightly closed and a sufficient quantity of amniotic fluid remains. If external version is successful, some writers advocate the use of the Willett clamp to maintain the fetal head in the pelvis. We have had no experience with this method.

Midlabor. Membranes intact. At this stage cesarean section remains feasible. As previously pointed out, hysterectomy may be performed in the multipara who is grossly infected. On the other hand, in the primipara every attempt should be made to save the uterus. Intrauterine bags are of questionable value in aiding in the further dilatation of the cervix and preventing prolapse of the cord or a small part. They may sometimes be used to control hemorrhage when placenta previa is discovered. Eastman advises the use of an intravaginal bag to exert counterpressure and so prevent rupture of the membranes. Our experience with the intravaginal bag has been limited and not satisfactory, for the bag has failed to prevent rupture of the membranes and has proved to be extremely painful.

Midlabor. Membranes ruptured. Here the treatment is much the same as outlined for midlabor and intact membranes. The intravaginal bag, however, has no use once the membranes are ruptured.

Terminal labor. Once the cervix is fully dilated or nearly so, internal podalic version and breech extraction may be carried out. The available statistics show that this method of treatment carries with it a high fetal and greater maternal mortality rate. It is one of the leading causes of uterine rupture, and, in transverse presentation this is particularly important, for the lower uterine segment is often very thin or a low implanted placenta may be present. A review of the maternal deaths reported in cases of transverse presentation always shows a large number of the deaths attributed to rupture of the uterus following internal podalic version and breech extraction, while the occasional case is due to infection or hemorrhage. At the Woman's Clinic of The New York Hospital, Pastore found the average blood loss at delivery to be 244 cubic centimeters. The 38 cases of transverse presentation delivered by internal podalic version and breech extraction had an

average blood loss of 335 cubic centimeters. Six of these cases suffered a postpartum hemorrhage (15.8%). We can only counsel as do Novey and Schneider, that unless certain requirements are satisfied (particularly a sound uterus, the absence of tumors, lack of disproportion and a sufficient quantity of amniotic fluid), internal podalic version is extremely hazardous. If these requirements are not satisfied internal podalic version should not be attempted, but rather the fetus be sacrificed in a destructive operation. When the cervix is fully dilated and the fetus dead, the least traumatic procedure attended by the smallest risk is a destructive operation, particularly exenteration.

DISCUSSION

An investigation of the high fetal mortality rate associated with transverse presentation revealed that 7 deaths occurred prior to the onset of labor, 8 were associated with labor and delivery, and 3 were neonatal deaths. The 1 maternal death is recorded in detail.

The treatment of transverse presentation is discussed at some length. In order further to reduce fetal and maternal mortality, stress should be placed on good antenatal care, the observance of certain precautions in anticipation of a difficult delivery, and the intelligent evaluation of the individual case as to method of delivery. The high mortality figures that accompany delivery from below are pointed out, and the complications that arise from unwise internal podalic version and breech extraction are emphasized. The development of blood banks and the recent advances in chemotherapy should further reduce the number of deaths. The more frequent employment of cesarean section as the method of delivery in transverse presentation is indicated because of the attendant low mortality figures.

SUMMARY

1. Seventy-eight cases of persistent transverse presentation occurring in approximately 45,000 deliveries at the Woman's Clinic of The New York Hospital are reported. A brief account is given of the probable etiological factors, and a tabulation of the cases according to parity again emphasizes the importance of multiparity.

2. One maternal (1.3%) and 18 fetal (23.1%) deaths are recorded. In 58 cases in which the fetal heart was audible on admission to the hospital and the infant weighed 2500 grams or over, 5 fetal deaths occurred (8.6%).

3. This series differs from others in that in 46.1 per cent of the cases delivery was by cesarean section, and in this group there were no fetal or maternal deaths.

NOTE.—Since this study was completed, in 5 further cases of transverse presentation delivery was by cesarean section without fatality.

GASTRIC CANCER: LAPAROTOMY, RESECTABILITY, AND MORTALITY

SAMUEL N. MAIMON, M.D., and WALTER LINCOLN PALMER, M.D., Chicago, Illinois

THE purpose of this paper is to analyze the present status of the surgical treatment of gastric cancer with respect primarily to exploratory laparotomy, resectability, and postoperative mortality.

The only effective treatment of gastric cancer at present is surgical resection. The progress made in the perfection of this procedure is indicated by the increasing number of patients submitted to operation, the lowered mortality rates, and the longer periods of postoperative survival. However, the published statistics are quite variable and evidence different concepts of operability and resectability as well as different mortality and survival rates.

From the Charity Hospital in New Orleans, Morris reports 1,163 patients with gastric cancer, admitted between 1932 and 1940, of which 829 were considered inoperable; 344 were subjected to operation with 138 hospital deaths. In a special group of 200 patients subjected to operation, the same author reports 55 gastrectomies with a mortality of 56 per cent. In 1931, the mortality of gastric resection at that institution was 51.4 per cent while in 1942, it was 16 per cent.

From Seattle (13) are reported 273 gastric cancers with only 12 resections and 6 survivors. Emmet describes 74 cases with 24 gastrectomies and a mortality of 20 per cent. At the Cincinnati General Hospital (22), between 1932 and 1936, 42 per cent of the patients with gastric cancer underwent operation with a resection rate of 9 per cent; by 1939, the resection rate had risen to 43 per cent. Thorstadt reports 454 patients from Harper Hospital with 57.7 per cent operability, 19.4 per cent resectability and a gastrectomy mortality of 64.7 per cent while at Receiving Hospital, a municipal institution, he

found 23.4 per cent of 516 patients operable and 9.8 per cent resectable with a gastrectomy mortality of 57 per cent. This percentage suggests that operability and resectability decreased as the economic level was lowered. Livingston and Pack quote Sandweiss (12, p. 15) to the effect that 7.7 per cent of the patients with gastric cancer in Detroit received resection and 3 per cent reached the stage of resection survival. In an extensive survey, Baron found 25 per cent of explored patients resectable with a 30 per cent resection mortality (3).

Table I shows that the operability of gastric cancer varies from less than 25 per cent at some institutions to more than 89 per cent at others while resection mortalities range from 4.9 per cent to 64 per cent. In order to avoid confusion these statistics must be carefully analyzed and interpreted particularly with respect to the following 4 factors: (1) the total number of patients with gastric cancer, (2) the number subjected to exploration, (3) the number in which resection of the primary growth is accomplished, and (4) the number of survivors in relation to the total.

ANALYSIS OF CASE DISPOSAL

At the University of Chicago over a 17 year period (1927 to 1944) some 576 patients with gastric carcinoma were examined. In a study of the disposition of the unselected total it was noted that laparotomy was advised in 71.8 per cent, not advised in 13.3 per cent and refused in 4.3 per cent. Of the group 67.5 per cent accepted exploration, 35.3 per cent underwent resection, and 26.05 per cent survived resection. A detailed examination of the case disposal, however, reveals that 85, or 14.7 per cent, of the 576 did not return for definitive advice or were admitted for special procedures such as gastroscopy. Of the 491 who did return for advice, laparotomy was not advised in 77 (16.5 per cent) refused in 25 (5.1 per

*Not stated ‡Cases

cent), and performed in 389 (78.4 per cent). Thus 466 patients, 80.9 per cent of the total group of 576, accepted the physician's advice and form the basis of a more accurate evaluation as to surgical intervention.

LAPAROTOMY AND RESECTABILITY

Of the 466 patients who followed the advice given laparotomy was carried out in 389 or 83.5 per cent; the remaining 16.5 per cent were considered inoperable. Metastases to the liver or to distant organs and carcinomatous involvement of the peritoneum constituted the major contraindications to operation. Exploration alone was carried out in 20.1 per cent while palliative procedures consisting of gastrostomy, gastroenterostomy and jejunostomy were performed in 19.7 per cent. Resection was possible (Table II) in 203 cases, 43.5 per cent. Partial resection was the most widely employed operation, 36 per cent (of 466) being subjected to this procedure. Total gastrectomy (transabdominal 3.5 per cent and transthoracic combined with partial esopha-

gectomy 4.2 per cent) formed a relatively small part of the effective surgical measures. The resection rate of 43.5 per cent is high and indicates that the procedure was undertaken in a number of patients who presented far more than the average risk. Approximately 25 per cent of the partial resections were complicated by metastatic involvement of neighboring organs. Partial resection of the liver, pancreas, colon, removal of the spleen, and extensive lymph node dissections were often performed. Of the total patients undergoing partial resection, 79.2 per cent survived and were discharged from the hospital; approximately half of the patients undergoing transthoracic and transabdominal total gastrectomy were discharged, the mortality in 35 patients subjected to these procedures being 51.4 per cent. A total of 150 patients survived gastrectomy of all types. Figured on the basis of the 466 patients who sought advice, these 150 represent 32.2 per cent; when figured on the basis of the 389 subjected to exploration they constitute 38.8 per cent.

TABLE II.—OPERATIVE PROCEDURE AND MORTALITY (466 CASES)

Procedure		Number of patients	Per cent of total	Operative mortality Per cent	Operative survival Per cent

POSTOPERATIVE MORTALITY

The mortality in the 389 operations was 23.3 per cent, 91 deaths (Table II). In the 203 resections of all types there were 53 deaths, a mortality of 26.1 per cent. In the 168 partial resections there were 35 deaths, 20.8 per cent. Examination of reported rates in the literature seems to reveal a downward trend in the reported rates of resection deaths in experienced hands, although the indications for operation and for resection have varied so greatly that one cannot be certain of this. In the present series, from 1929 to 1940, there were 119 partial resections with a mortality of 22.6 per cent with an operative survival of 77.4 per cent while from 1940 to 1944 there were 49 partial resections, with a mortality of 16.3 per cent with an operative survival of 83.6 per cent. Finsterer reports a mortality of 6 per cent for uncomplicated resection and of 39 per cent for complicated partial resection. Wesc found a 17.3 per cent mortality for simple resection and 41 per cent for complicated resections. These figures are somewhat difficult to interpret for the terms "uncomplicated" and "complicated resection" may be defined somewhat differently. Brunschwig has advanced the thought that partial resection of the stomach is comparable to simple mastectomy whereas "complicated" or "radical gastrectomy" is comparable to radical mastectomy wherein extensive lymph node and neighborhood structures are resected in an effort to remove or prevent metastases.

The high mortality for transthoracic resection may be due to the small number of cases

or it may reflect the initial surgical experience with this procedure in this institution. More favorable progress is indicated by a recent report for this operation in this institution by Phemister and Adams of 33 transthoracic resections for carcinoma of the cardiac end of the stomach or the lower esophagus with 21 survivors; in a later series (Adams) there were 8 survivors in 10 such resections.

A mortality of 13.6 per cent was noted for exploratory laparotomy only. Palliative operations, gastroenterostomy, gastrostomy and jejunostomy, had a mortality rate of 26.1 per cent—the same as that for all types of resection and presumably not offering the degree of palliation provided by resection. Anschutz reports that palliative resection in his hands carried a 32 per cent mortality but allowed 34 per cent of 99 patients to survive 1 year, 21 per cent to survive 3 years, 8 per cent to survive 5 years, and 5 per cent to survive 8, 10, and 15 years. This suggests that more attention be focused on palliative resection as a substitute for gastroenterostomy, gastrostomy, and jejunostomy.

POSTOPERATIVE DEATHS

In 35 deaths following partial or total gastrectomy, 7 were associated with the extensive removal of other viscera because of neoplastic involvement; 18 followed total transthoracic or transabdominal gastrectomy. Fifteen patients died between the 1st and 3rd postoperative days; 16 between the 3rd and 7th days; 5 between the 14th and 21st days and 5 between the 21st and 29th days. Thus 31

patients, or 58.5 per cent of the deaths, died during the first postoperative week.

In 25 per cent of the patients dying postoperatively after resection, no detectable metastases were found at autopsy. This fact suggests that at least 25 per cent of the patients undergoing resection have a good chance of surviving 5 years or longer. In a recent report by Metheny (14) of 143 patients who died without operation, the lesion was confined to the stomach in 10 per cent and was theoretically curable by resection in 18 per cent.

Peritonitis, the chief cause of death (Table III) was due in some cases to suture leakage; in others the suture lines were intact. Pneumonia was the next important complication in 8 cases and directly caused death in 6. Other occasional causes of death were: shock from extensive operative procedures, mediastinitis, pulmonary embolism, pancreatic abscess, and granulocytopenia.

DISCUSSION

It is evident (Table I) that to a certain extent the indications for operation and resection in gastric cancer are matters of opinion, one report indicating that only 23.4 per cent of the patients were considered suitable for laparotomy whereas in another the figure is 89 per cent. Some clinics and groups with large experience lean toward the conservative view while other groups hold the more radical views. In this series the laparotomy rate was 83.5 per cent, higher than any we have found in the literature with the exception of the 89.9 per cent reported by Bocharov. Likewise, the resectability rate of 43.5 per cent was the highest found in the literature with the exception of the 44.6 per cent rate reported by Lahey. These figures probably reflect in part the difficulty in determining the possibility of resection without operation. The present trend is definitely toward a higher laparotomy rate and the acceptance of greater hazards in resection. This trend results from recognition of the following facts: (1) surgery offers the only hope of cure, (2) palliative resection is very much worth while, and (3) the mortality rate has progressively diminished in spite of the acceptance of greater hazards, the diminu-

TABLE III.—CAUSE OF DEATH

tion being due to greater surgical skill, immediate prophylactic treatment of shock with transfusions of blood and plasma, and improved preoperative and postoperative care.

The factors responsible for the variations in resection mortality are not always available from reports. Livingston and Pack found only 3 instances in the United States, of published records of over 100 total gastrectomies for gastric cancer prior to 1939 and only 3,000 partial resections. Of all institutions reporting, 98 per cent had less than 2 resections per week while the great majority had less than 6 per year.

SUMMARY

1. Of 576 patients in whom the diagnosis of gastric carcinoma was made, 491, or 85.3 per cent, came for definitive advice and 466, or 80.9 per cent, accepted the advice.

2. In this group of 466, laparotomy was recommended and carried out in 389, or 83.5 per cent.

3. The resectability rate based on the 466 was 43.5 per cent; when based on the 389 submitted to exploration it was 52.1 per cent.

4. The resection survival rate based on the total of 466 was 32.2 per cent, when based on the 203 patients undergoing resection it was 73.7 per cent.

5. The mortality for gastric resection of all types was 26.1 per cent for the 17 years.

6. The mortality in unselected cases of partial resection was 22.6 per cent before 1940, 16.3 per cent after 1940.

7. Peritonitis continues to be the chief cause of postoperative death.

8. No residual carcinoma was demonstrated at autopsy in 25 per cent of the patients dying postoperatively from gastric resection.

CONCLUSIONS

The data herein presented seem to us to indicate:

1. A definite increase in the percentage of patients considered operable.
2. Higher resectability rates.
3. Lower postoperative mortalities in spite of the greater incidence of complicated and extensive operations.

Considerable progress is thus being made in the only treatment offering any real hope at the present time, namely surgical removal; nevertheless, the outlook for prolonged survival continues to be rather limited.

BILATERAL AND MULTIPLE RUPTURED DISCS AS ONE CAUSE OF PERSISTENT SYMPTOMS FOLLOWING OPERATION FOR A HERNIATED DISC

FRANCIS A. ECHLIN, M.D., F.A.C.S., New York, New York, BERTRAM SELVERSTONE, M.D.,
Captain M.C., A.U.S., WALTER E. SCRIBNER, M.D., Major, M.C., A.U.S.

IT has been firmly established that the acute symptoms due to a herniated lumbar disc can be relieved by removal of the offending disc in most cases. Permanent relief of acute symptoms has also occurred in a large proportion of patients who have been able to avoid undue physical strain after operation.

On the other hand most surgeons will agree that recurrence or, less often persistence, of moderate to severe symptoms following operation for a herniated lumbar disc is by no means uncommon, especially when the patient has undertaken heavy work. The cause of these symptoms is usually obscure. In the great majority of instances they have occurred in patients who have been suffering from a solitary herniation which has apparently been adequately removed. Multiple herniations cannot therefore account for the symptoms in this group. In the present paper further observations (5) are presented, however, which support the belief that these recurrent or persistent symptoms may, at times, be due to the presence of bilateral or multiple ruptured discs which may be overlooked at the first operation.

In 1939 Camp, on the basis of myelographic studies, reported that in his experience 12 per cent of herniated discs were multiple. In the same year Love suggested that in order to avoid overlooking multiple discs it might be wise to use contrast media in all cases, even though protruded discs could be recognized clinically. Since then the occurrence of bilateral or multiple herniated discs has been reported by many observers (1, 2, 3, 6, 7, 8, 9, 13, and others). Childe has remarked, "Multiple disc herniations in the lower lumbar

From the neurosurgical centers and x-ray branches at De Witt General Hospital, Auburn, California, and McCloskey General Hospital, Temple, Texas.

region are much more frequent than was originally supposed, and this is another strong argument in favor of routine myelography. All possible combinations exist and as many as six have been diagnosed in one individual." Dandy's observations in 1944 have served to focus our attention even more acutely on this problem for he has stated that, "Inspection of the spinal column explains the cause of defective lumbar discs, their frequency and the fact that they are nearly always multiple or potentially multiple. The high incidence of multiple discs is to be expected and actually obtains in practically all cases."

The problem of diagnosis and treatment in ruptured lumbar disc is far from solved. The present paper stresses one of the reasons why the problem is so complex and perhaps insoluble in certain cases.

In a report of a previous series of cases (5) it was re-emphasized that bilateral or multiple disc herniations may give rise to symptoms suggesting the presence of only a solitary unilateral herniation. For this reason a diagnosis based on clinical findings alone may be unreliable and it is believed that preoperative pantopaque myelographic studies (5, 12, 14, 15, 16, 17) are indicated in all these cases as a helpful adjunct to clinical diagnosis. That myelography also may fail to reveal a disc protrusion is, of course, well known. This fact makes it more apparent that multiple discs are even more common than has been demonstrated.

During the past 10 months (August 1944 to May 1945) 60 patients were operated on for a suspected herniation of a lumbar disc. In 56 of these cases one or more herniated discs were found. In the other 4 patients nothing abnormal was revealed at operation. The preoperative myelograms in the 4 cases had

on both the right and left side. The thinned posterior longitudinal ligament¹ was incised over the dome of the protrusion on the left and several small pieces of nucleus pulposus, which had herniated through the ruptured annulus were withdrawn by traction. A thorough extirpation of remaining nucleus pulposus tissue was then accomplished. The removal was carried across the midline after further retraction of nerve root and dura. Attention was then again turned to the disc herniation on the right and it was found to have been completely unchanged by the extirpation on the opposite side. This portion of herniated disc was then removed in similar fashion to that on the left. At the completion of this procedure it was found that the posterior longitudinal ligament had been incised, and intervertebral disc excised, directly across the midline. This had proved necessary before the posterior herniation of the disc on the right could be relieved. These findings demonstrated to us that when a bilateral herniation of an intervertebral disc exists, removal of the disc from a unilateral approach may not be sufficient to relieve the posterior herniation on the opposite side. In the second case with a bilateral herniation of the nucleus pulposus (Fig. 2) a similar bilateral exploration was performed but this time at the fifth lumbar level. Again a bilateral herniation of the disc was present with bilateral compression of the nerve root. The disc tissue in this case was considerably firmer than in the patient just described and was very difficult to remove. As in the first case, removal on one side had no apparent effect on the degree of herniation on the opposite side, although in this instance extirpation was not carried across the midline. The third case in this group of bilateral herniated discs presented a picture essentially the same as the other two. Myelogram showed a large bilateral filling defect (Fig. 3, a and b). At operation a large protrusion with definite compression of nerve root was visualized bilaterally before removal was attempted. The disc was then approached from the right side and found to be definitely

herniated. The herniated portion of the nucleus was grasped with forceps and by means of traction as much tissue as possible was withdrawn. With the Cushing pituitary rongeur as radical a removal was then carried out as we are capable of doing. The rongeur was thrust downward into the depths of the intervertebral disc and tissue removed in a lateral and anterior direction at first, until all available material was obtained down to the firm fibrocartilaginous portion of the disc. The rongeur was then reversed and removal carried toward the midline and anteriorly until the nose of the rongeur again everywhere freely contacted firm resistance at the anterior limit of the disc. During this procedure the rongeur was at intervals angulated slightly in order to grasp any nucleus pulposus material adherent to the surface of the bodies. This method has proved more satisfactory in our hands than currettting the opposing surface of the vertebral bodies. This was regarded as rather a test case, and hence every effort was made to remove as much of the disc as seemed safely possible. Despite this radical removal on the right, the left-sided protrusion remained intact and had to be removed separately. This protrusion also proved to be a definite herniation of the nucleus pulposus. The large amount of disc tissue obtained from each side is shown in Figure 4. As previously stated, the clinical findings in the 3 patients just reported indicated a unilateral herniated disc. The first patient, however, did give a history of radiation of pain toward the right buttock on several occasions in addition to his usual severe pain which was distributed throughout the course of the left sciatic nerve. Following myelogram the pain began to radiate down the right leg as well as the left. The operative findings of bilateral root compression in the 3 cases cited, we feel, are very good evidence that none of these individuals might have been relieved of symptoms by a unilateral operation (at least in our hands) which would have been the case if clinical symptoms alone, without myelogram, had been relied upon.

It should be mentioned here that in 2 other cases in this series a bilateral protrusion of the disc, demonstrated in the myelogram and

¹By longitudinal ligament reference is made to that thin membrane or capsule which usually overlies the herniated portion of the nucleus pulposus. This membrane is continuous with the longitudinal ligament but also forms the posterior layer of the annulus fibrosus.

Fig. 1. This pantopaque myelogram shows an almost complete block at the fourth lumbar interspace (arrows). Pantopaque was injected at the third lumbar level and the patient placed in the upright position. Fluoroscopy and subsequent x-ray examination revealed that only a small amount of the material was able to trickle past the block and pool at the interspace below. At operation a bilateral herniation of the nucleus pulposus was found and a bilateral operation was required to remove it. Clinically the patient was believed to have a herniated disc only on the left side.

Fig. 2. A bilateral filling defect is seen at the arrows. This defect was constant as revealed by fluoroscopy and repeat x-ray films. A bilateral operation was necessary to extirpate a herniated disc which was found to be present on each side at this level (lumbar five). The clinical findings indicated a unilateral herniated disc.

Fig. 3. Myelogram, a, shows a complete filling defect at the level of the fourth lumbar disc. In myelogram, b, same patient, there is a bilateral filling defect at lumbar four interspace. Fluoroscopy left no doubt that a large bilateral defect was present. A bilateral herniation was found at operation and required a bilateral operation to decompress the nerve root on each side. A photograph of

the intervertebral disc material removed at operation is shown in Figure 4.

Fig. 4. The photograph shows intervertebral disc tissue removed at operation from the patient whose myelogram is seen in Figure 3. During the operation a herniation of the fourth lumbar disc was found on the right side and an attempt was made to remove as much as possible of the disc from a right sided approach. Photograph a shows the amount of material obtained. Despite this large extirpation of disc substance a marked herniation of the disc persisted on the opposite side and had to be removed through a left sided approach. Photograph b shows the amount of disc tissue obtained from the left side.

Fig. 5. a, The column of pantopaque stops abruptly at the third lumbar disc where an apparently complete block exists (arrows). The material was injected at the second lumbar interspace and the patient during fluoroscopy was left in the upright position for about 20 minutes but the pantopaque failed to descend below third lumbar inter-

(Continued on next page)

Fig. 7.

a Fig. 8. b

a Fig. 9. b

space. b. This is a myelogram done on the same patient several days later. The material was injected at lumbar five interspace and ran upward slowly. When the patient was again tilted into the erect position the pantopaque remained very nearly stationary, as shown, indicating an almost complete block at the third, fourth, and fifth lumbar discs (arrows). A large herniation of the disc was found at lumbar three, four, and five levels on the right (the side of the sciatic pain). The left side was not explored. Clinically the patient was thought to be suffering from a herniation of the fifth disc on the right. After myelography operation was postponed for several weeks as we thought at first we were dealing with a diffuse arachnoiditis.

Fig. 6. Two filling defects are revealed in this myelogram, one at the fourth interspace, a, and the other at the fifth, b. Fluoroscopy and repeat x-ray film revealed the defects to be constant and reproducible. Each filling defect outlined a herniated disc as proved at operation. The patient clinically was believed to have only one ruptured disc.

Fig. 7. A unilateral filling defect is seen at the site of the third (top arrow) and fourth (bottom arrow) intervertebral discs. A herniation of both the third and fourth discs was found at the time of operation, even though clinically the patient presented the signs and symptoms of a solitary ruptured disc.

Fig. 8. The patient on whom this myelogram was performed had a large herniation of the disc at lumbar four, a, and at lumbar five level, b. Fluoroscopy demonstrated an almost complete block at lumbar four interspace and a large unilateral filling defect at lumbar five interspace. His clinical symptoms indicated a herniation of only the fifth disc.

Fig. 9. This is another example where myelography indicated the presence of two herniated discs in a patient who clinically was believed to have only one herniation. At operation a rupture of the fourth disc was proved to be present at the indentation of the pantopaque column as seen in a, and a herniation of the fifth disc at the site of the defect demonstrated in b.

Fig. 10.

Fig. 11.

Fig. 12.

Fig. 10. Myelography showed a large filling defect at the level of the fourth lumbar disc on the right side (top arrow). The lower arrow points to the area of bone removal where a herniated disc (fifth lumbar) was extirpated previously. The patient had persistence of symptoms on the right side following the initial operation. At a second operation a large herniation of the disc was found at the site of the filling defect.

Fig. 11. The filling defect noted at the level of the fourth lumbar disc (top arrow) outlines what proved at

operation to be a large herniation of the disc. The patient on whom we performed this myelogram had had a protruded disc removed elsewhere from the fifth lumbar interspace (bottom arrow).

Fig. 12. Filling defects are present in the pantopaque column at the level of the fourth (middle arrow) and the fifth lumbar discs (bottom arrow). Herniated discs were found at the site of each filling defect. The patient had had a negative operative exploration done elsewhere at lumbar three level (top arrow).

there was a large herniation of the disc at the fifth interspace on the right side, and that this disc was removed. Following this procedure the patient continued to complain of low back and right sciatic pain although he believed this to be somewhat less severe than before operation. A pantopaque myelogram (Fig. 10) was performed by us and revealed a large filling defect on the same side as the original exploration but at the interspace above. At a second operation we removed a disc from the fourth interspace, which was markedly herniated and which caused severe pressure on the nerve root. The history of the second patient was very similar to the one just mentioned and also similar to a case reported by Echols. An accomplished neurosurgeon had removed what, from the operative report, appears to have been a definitely ruptured

intervertebral disc at the fifth lumbar interspace. The patient had complete relief of symptoms for a short period but during bicycle riding had a severe recurrence of his old symptoms. We performed a myelogram (Fig. 11) which revealed filling defects at the site of the old operation and also at the interspace above. At a second operation a large herniation of the disc was found at lumbar four level and extirpated with relief of symptoms. In this case it is possible that the herniation of the fourth lumbar disc occurred after the original operation. However, since no myelogram was performed initially, one is left in doubt concerning this possibility. The third patient in this group had been explored by an excellent surgeon overseas at the third lumbar interspace which he had mistaken for the fourth. His exploration was negative and

the patient continued to complain of symptoms. In a subsequent myelogram (Fig. 12) unilateral filling defects were present at the level of the fourth and fifth discs, on the same side as the first operation. At a second exploration we found a ruptured disc at the site of each filling defect.

The final case in the series was a patient who had a herniated disc removed by a well known neurosurgeon overseas from the fifth lumbar interspace on the right. As a result of this his right sciatic pain disappeared but he continued to complain of low back pain and later of pain down the left sciatic distribution. Myelogram was performed and revealed nothing abnormal. The orthopedic service, on good evidence, believed that spinal fusion might help this man and this was accordingly carried out. During the procedure one of us was asked to explore the fifth interspace on the left side. This was done. The posterior longitudinal ligament was found to be bulging slightly and on palpation felt soft and rubbery. It could not be stated definitely that the nerve root in this case was compressed at the time of exploration. However, on incising the post longitudinal ligament the deeper portion of the annulus fibrosus was found to be ruptured and a piece of intervertebral disc of "Y" shape, each limb of the "Y" measuring approximately 1 by $\frac{1}{2}$ inch, was lifted out of the intervertebral space. This very large piece of intervertebral disc was completely unattached to surrounding tissue and lay free in the intervertebral space between the bodies. (It should be noted that this is the only case included in the group of multiple or bilateral discs in which evidence of nerve root compression was lacking.)

COMMENT

Experience in the Army has not proved the problem of herniated disc to be a simple one. Recurrence, or less often persistence, of moderate to severe symptoms, both organic and functional, following operation has been only too frequent, especially when the individual has been required to do heavy work. In the Army a functional element has probably played a greater rôle in precipitating these

symptoms than in civilian life, but in many patients the causative factors are not clear; at least there is a wide difference of opinion concerning their etiology (11). The great majority of patients who have presented such symptoms have suffered from a solitary herniated disc which was apparently adequately removed. As pointed out multiple herniations cannot therefore account for the symptoms in this group. It is believed, however, that the series of cases reported illustrates that bilateral 6.6 per cent of 60 cases or multiple 16.6 per cent of 60 cases herniated discs which may be overlooked at the first operation, may at times account for these persistent or recurrent symptoms.

Clinical findings alone will usually fail to indicate the presence of more than one herniated disc and therefore cannot be safely relied upon to disclose the multiple lesions under discussion. Myelographic studies with pantopaque are very helpful in revealing the presence and level of such lesions and in our opinion are indicated in all cases before operation. This procedure, however, may occasionally also fail to reveal a ruptured disc, especially when it lies far laterally. In the presence of a negative myelogram, decision to operate will depend upon the severity of the symptoms and whether or not the clinical picture is characteristic of a herniated disc. Likewise decision to explore multiple defects will depend upon their nature, the patient's symptoms, and the surgeons' clinical judgment.

In selecting cases of suspected herniated disc for myelography we have adhered to a conservative policy. Only those patients with intractable, characteristic symptoms of herniated disc, who have not responded satisfactorily to conservative orthopedic measures have been subjected to this diagnostic procedure. No patients have been operated upon without it. We believe that this is sound policy. As a result we were dealing with relatively severe cases and this may explain in part the high incidence of multiple herniations.

It should be emphasized that although the removal of multiple ruptured discs will usually relieve acute symptoms, heavy work is prob-

ably more likely to precipitate postoperative symptoms in this group than in patients who have required the removal of only a single disc. The fact that multiple discs are relatively common therefore only emphasizes the complexity of the problem.

METASTATIC HYPERNEPHROMA OF THE THYROID GLAND

ROBERT R. LINTON, M.D., F.A.C.S., J. DELLINGER BARNEY, M.D., F.A.C.S., HENRY D. MOORMAN, M.D., and JACOB LERMAN, M.D., Boston, Massachusetts

THE rarity of metastases to the thyroid gland from primary malignant foci elsewhere in the body is well recognized.

Willis in 1931 reviewed the literature in reference to metastatic tumors of the thyroid. He collected 47 cases and added 10 more of his own. His cases were taken from 170 consecutive autopsies in patients who died of malignant disease—an incidence of 5.9 per cent. Other series of autopsies in cases of extensive carcinoma which he collected gave percentages varying from 1.5 (15) to 3.1 (7). Rice found, in a series of 89 autopsies on patients who died from malignant tumors, 9 or 10 per cent of the thyroids showing metastatic tumor cells. These could be seen grossly in 5 cases and were found only on careful microscopic sectioning in the other 4. He stressed the need for more careful study of the thyroid gland in such autopsies. Mayo and Schlicke, in 1941, reviewed all the cases of metastases to the thyroid which had been encountered at the Mayo Clinic. They found 19 cases and in 3

the diagnosis was made from thyroid specimens removed at operation. Two of these cases were metastases from hypernephromas and one from a carcinoma of the rectum. Seven cases had thyroid abnormalities noted before death and the remaining 9 cases were encountered during routine autopsy examination. The total number of autopsies done was not given, but in more than 45,000 cases in which thyroidectomy was performed only 3 metastatic lesions were found.

Explanations for the infrequency of metastases in the thyroid have been sought in 2 directions; one group postulating that the very rich arterial supply inhibits the lodgment of emboli in the gland, while others were of the opinion that the rarity is due to chemical factors which hinder metastatic growth. Paget spoke of some tissues which he considered "congenial soil" for malignant tumors. The high oxygen and high iodine content of the gland may be factors which inhibit the development of malignant cells. In contrast the relatively low oxygen saturation of liver tissue may predispose to the frequency of neoplastic spread to this organ. Warburg has

Fig. 1. A photomicrograph from the original hypernephroma. The tumor was removed when the left nephrectomy was performed in 1936. The cellular structure is similar to that seen in Figures 3 and 4.

pointed out that tumor cells can grow at a relatively low oxygen tension.

Willis concluded that chemical factors largely explain the scarcity of metastatic lesions in the thyroid. He found that in several of his cases adenomatous and fibrous changes in the thyroid had preceded metastases and he felt that the lower oxygen and iodine content predisposed to the establishment of these metastases. Similarly, Mayo and Schlicke found underlying adenomatous changes in 12 (and perhaps in 4 others) of their 19 cases. The thyroid in the case presented here also showed the same underlying pathology. It seems to us, however, that such changes in the thyroid gland tend to support the theory that the rich blood supply of the organ hinders the lodgment of tumor emboli, since fibrotic areas and degenerating adenomas probably have a reduced blood supply compared to normal thyroid tissue, so that the tumor emboli may be deposited more readily in these areas. It also seems probable that the sieve-like action of the lungs is an important factor in decreasing the number of tumor emboli which might otherwise lodge in the thyroid. Willis further found in his series that malignant melanomas and primary lung carcinomas, although relatively uncommon tumors, were found to have metastatic foci in the thyroid in a proportionately higher num-

ber of cases. He concluded from the data that different types of tumors possess different intrinsic capacities for establishing metastases in the thyroid. Miller and Jones, however, collected 808 cases of primary lung cancer and found only 8 cases in which there were metastases to the thyroid, an incidence of only 1 per cent.

A review of the literature reveals that only 15 proved cases of metastatic hypernephroma of the thyroid have been reported. Since this lesion is of such rarity it seems justifiable to report an additional case.

According to H'Doubler the first 5 cases were reported in the European literature. These were by Lubarsch, in 1894, Kodzibowski, in 1904, Pistocchi, in 1922, Rost, in 1912, and Klose, in 1925. The first 3 cases were recognized clinically, but the last 2 were discovered on routine autopsy. Since 1931, 10 additional ones have been reported, 9 in the American literature and 1 in the French literature. Kolodny, in 1926, reported a case which he considered metastatic hypernephroma of the thyroid with an accompanying clinical picture of exophthalmic goiter, but considerable doubt has arisen in regard to the case. The gland was removed and found to contain many circumscribed yellowish white nodules which Kolodny believed on microscopic examination to be metastatic hypernephroma. The patient, however, remained in good health with relief of her symptoms and no primary tumor was found. This case on further analysis probably was not a metastatic hypernephroma and, therefore, is not included in the group of cases reviewed here, especially since Simpson, in 1926, reported 8 cases out of a group of 55 malignant thyroid glands in which he found microscopically groups of cells that simulated hypernephroma. He concluded that Kolodny's case represented this type of tumor.

Willis, in 1931, reported the first authentic case in the American literature of metastatic hypernephroma of the thyroid gland. The condition was discovered on postmortem examination. The thyroid gland was found to show fibrosis and parenchymatous atrophy. Pemberton and Bennett, in 1934, reported 2 cases from a series of 45,421 surgical thyroid

Fig. 2. a, left, A photograph of the entire thyroid gland removed in one piece at operation on April 13, 1944. Note the lobulated appearance of the specimen. b, A photo-

graph after section of the specimen to show the metastatic nodules of tumor tissue throughout the substance of the thyroid gland.

specimens removed at the Mayo Clinic between 1892 and 1932.

H'Doubler, in 1936, reported 2 cases. The first, a man aged 59 years, presented the classical symptoms of hyperthyroidism with a basal metabolic rate of plus 46. One year previously he had noted bloody urine. Physical examination showed an enlarged right lobe of the thyroid gland. This was removed at operation and was found to be a canary yellow nodule, which on histologic examination proved to be typical of hypernephroma. The patient died 3 years later from generalized metastatic renal cell carcinoma. The second, a woman aged 73 years, complained of choking spells and a goiter. Six years before, a hypernephroma of the right kidney had been removed. She had noted a lump in her thyroid gland 3 years later which had gradually increased in size. Physical examination showed an enlarged, firm right lobe of the thyroid gland. An operation was performed, at which the right lobe, the isthmus, and an accessory nodule were removed. One and a half years later a nodule developed in the left lobe. She died 4 years after the operation of generalized metastases.

Caylor and Caylor, in 1936, reported 1 case, a man aged 59 years, who had had a transperitoneal nephrectomy for hypernephroma. Thirteen years later, at operation, an inoperable metastasis was found in the

thyroid gland. He was given roentgen therapy with some improvement.

Weiskittel, in 1937, reported 1 case among 10,000 thyroidectomies at the DeCourcy Clinic. The patient, a man aged 60 years, 8 years previously had had a right nephrectomy for a hypernephroma. He later noted a painless swelling of the neck. Physical examination revealed an enlarged, firm thyroid gland. A basal metabolic rate was plus 32. At operation a large metastatic renal cell carcinoma was removed. The wound was packed open because of extensive bleeding. He was given postoperative roentgen therapy but died 9 months later.

Fey and Truffert, in 1938, reported a case that had succumbed to extensive metastatic hypernephroma and necropsy revealed involvement of the thyroid gland. It is of interest that 16 years before a thyroid adenoma had been removed.

Welti and Huguenin, in 1939, reported 1 case of metastatic hypernephroma in a series of 88 cases of thyroid malignancy. The patient presented mild symptoms of hyperthyroidism. One kidney had been removed 10 years before for carcinoma. The patient died later of extensive metastases.

Long and Black, in 1945, reported a third case from the Mayo Clinic. The patient, a man aged 59 years, complained of a slowly enlarging goiter of 1 year's duration. Eight

years previously a nephrectomy had been performed for a hypernephroma. Physical examination revealed a diffusely enlarged thyroid gland of soft consistency. A resection of both lobes and the isthmus was performed. The histologic examination revealed metastatic hypernephroma. Postoperative roentgen therapy was administered.

CASE REPORT

Frank C., a man aged 55 years, was admitted to The Baker Memorial Hospital on March 30, 1944, complaining of swelling in the neck, ease of fatigability and weight loss, of about 6 months' duration.

About 6 months before entry following a severe upper respiratory infection, he noted the insidious onset of increasing ease of fatigue and was troubled with persistent left frontal headaches which were aggravated on lying down. He lost his appetite, became "nervous and irritable" and about 4 months before entry began to note a slowly increasing swelling in his neck. His weight fell from a normal of 204 to 186 pounds. During the month previous to admission the swelling increased rapidly and he began to have a "scratchy" feeling in his throat on swallowing but had no real hoarseness or dysphagia. He noted no tremor, palpitation, or increased prominence of the eyes.

Because of the cervical tumor, he was studied first in the hospital in which he worked. There it was found that his blood examination was within normal limits; his blood pressure was 116 systolic and 70 diastolic. His basal metabolic rate was minus 3. The blood cholesterol was 140 milligrams per cent. A barium enema, a cholecystogram, and a gastro-

intestinal series of roentgenograms were all negative. Intravenous pycnography showed an enlarged right kidney. No shadow was seen on the left which was consistent with his left nephrectomy 9 years previously. After the completion of these studies he was referred to The Baker Memorial Hospital for further study and treatment with a presumptive diagnosis of thyroiditis.

The patient was born in Portugal, coming to the United States at the age of 13 years. For several years he worked at varied occupations but for the past 26 years he had been a mechanic in a hospital. He had been married 31 years; his wife was living and well. They had had one child who died at birth. Nine years before this hospital admission a left nephrectomy was performed by Dr. C. L. Deming at the William Backus Hospital in Norwich, Connecticut. A renal cell carcinoma of the hypernephroma type was diagnosed pathologically (Fig. 1). He recovered uneventfully from the operation and, until his present illness, had enjoyed good health. He had had no other operations or serious illnesses. His system review was negative except for chronic sinusitis and a slight chronic nonproductive cough. He had occasional nocturia, but noted no hematuria or frequency. He smoked about ten cigarettes a day but did not use alcohol.

His family history was noncontributory and he knew of no familial incidence of cancer, tuberculosis, heart disease, diabetes, thyroid disease, or allergies.

Examination showed a well developed and nourished man with an obvious enlargement in his anterior cervical region, which was consistent with a symmetrical, diffusely enlarged thyroid gland with a slightly irregular outline. The gland was firm, but not stony hard and moved normally on swallowing. No regional nodes were palpated and no bruit was

LINTON ET AL: METASTATIC HYPERNEPHROMA OF THYROID GL.

present. The patient showed no signs of hyperthyroidism or hypothyroidism. Examination of the abdomen revealed a movable, nontender, rounded mass in the region of the right kidney, which descended to the level of the iliac crest on respiration. Physical examination was otherwise negative.

Blood count was 4.54 million; photohemoglobin, 13.2 grams per cent; white blood count, 8,600; the blood smear showed normal platelets, red and white blood cells. Urine examination showed specific gravity 1.008 to 1.020; one plus albumin; negative sugar; sediment, 0-20 red blood cells, 3-20 white blood cells and an occasional hyaline cast per cent in 2 hours. Blood chemistry examinations showed: nonprotein nitrogen, 27 milligrams per cent; fasting blood sugar, 119 milligrams per cent; cholesterol 266 milligrams per cent; phosphorus, 3.3 milligrams per cent; serum protein 7 grams per cent. The prothrombin time was normal and the blood Hinton test was negative. The basal metabolic rate was minus 3. Roentgen examinations revealed the following: The chest plate showed a slightly enlarged heart in the region of the left ventricle, but no evidence of substernal goiter. Retrograde pyelograms showed the right pelvis well outlined. The infundibula were narrowed with an appearance of crescentic pressure. The kidney shadow showed marked general enlargement with a slightly lobular contour. A diagnosis of congenital polycystic kidney was considered to be the most likely diagnosis from study of these roentgenograms.

Diagnosis: Malignancy of the thyroid gland.

On April 13, 1944, operation was performed. Endotracheal ether anesthesia was used. Through a transverse collar incision, an enlarged vascular thyroid gland was exposed. Biopsy specimens showed yellowish tissue, suggestive of hypernephroma. The right lateral thyroid vein was found to be filled with tumor-like tissue and accordingly it was believed that the thyroid enlargement was due to malignant growth, so a total thyroidectomy was performed. The recurrent laryngeal nerves and two parathyroid glands were visualized and preserved. The tumor was not adherent except over the cricoid cartilage. No enlarged nodes were seen or felt along the carotid sheaths and the lateral thyroid veins were ligated proximal to any obvious tumor. The tracheal neck dissection was not felt indicated. The wound was closed in layers without drainage. Cotton ligatures and sutures were used for hemostasis and wound closure.

Pathological examination of the specimen showed a 7 by 2 by 1.5 centimeter gland which weighed 72 grams. It was made up of round, solid, lobulated yellow-orange nodules measuring 0.5 to 2.0 centimeters in diameter. The right middle and inferior thyroid veins were filled with similar tissue (Fig. 2). The thyroid tissue between the nodules was red-

brown, firm and meaty. Microscopically was consistent with renal cell carcinoma.

The immediate postoperative course was uneventful except for slight transitory response to peroral administration of gluconate. Postoperative roentgen ray of the cervical region was not advised by department, so the patient was discharged hospital on April 26, 1944.

Following his discharge he developed which responded to the administration extract. He remained fairly well at home severe headaches and pains in his cervical region.

He was readmitted to The Baker Hospital on September 13, 1944, 4½ months after his first discharge, complaining of an increase in pain in the right side of his abdomen and examination showed the patient still in a state of malnutrition. His thyroidectomy scar healed. No evidence of recurrence of the tumor was found in his neck. The mass in his right chest enlarged considerably.

Laboratory studies at this time showed count, 3.85 million; photohemoglobin, 13.2 grams per cent. Urine examination revealed specific gravity, 1.012; negative albumin and sediment, occasional white blood cells and no casts. Blood chemistry examinations revealed: protein nitrogen, 33 milligrams per cent; phosphorus, 3.3 milligrams per cent; serum phosphatase, 2 units (1 unit = 100 units per cent). Roentgen examination of the chest at this time was negative.

On September 22, 1944, with patient under general anesthesia, the right kidney was exposed. A large renal tumor was found that could not be removed. A biopsy specimen was taken which showed renal cell carcinoma.

The postoperative course was uneventful. The patient was given palliative roentgen-ray treatment of his right kidney to a total of 1200 r each to the anterior, posterior, and lateral fields.

The latest report from the patient was following discharge. At that time he stated he felt well and wished to return to work.

This case, as far as can be determined, is the 16th case of metastatic renal cell carcinoma of the thyroid to be reported in the literature. Several of these, however, were confirmed by routine autopsy and undoubtedly there have been others which have not been reported. Those cases in which the metastases were recognized clinically and upon which a diagnosis was performed are of extreme interest in the differential diagnosis of thyroid carcinoma, especially in those patients who have previously had surgery performed for renal cell carcinoma.

The question of the manner in which metastatic emboli reach the thyroid from the kidney is still obscure, since if it is by the blood stream these organs are separated by the extensive capillary bed in the lungs. The persistence of a patent foramen ovale is one possibility whereby tumor cells could by-pass the pulmonary circulation to produce a paradoxical metastasis. The work of Batson has postulated the vertebral system of veins as another pathway by which such metastases may travel without going through the lungs. This also could be an explanation of the lack of pulmonary metastases in this and similar cases.

In the case reported the fact that a hypernephroma was found in the right kidney 9 years after a left nephrectomy had been done for a similar type of tumor, is of interest. This could be interpreted as a case of bilateral primary hypernephroma, although it is likely that the tumor in the right kidney was a metastasis from the original lesion. Forsythe, in 1942, reported a case of bilateral hypernephroma and found only 6 other cases, some of which were probably metastatic lesions rather than separate tumors. Beilin and Neiman in the same year reported another case and stated that direct metastasis from one kidney to the opposite is unusual. The origin of the thyroid metastases in the case reported may have been from either the right or left kidney, since the microscopic examination of the 3 specimens is identical. In view of the lapse of 9 years between the removal of his left kidney and the discovery of thyroid metastases, it seems most likely that they arose from existing tumor of the right kidney. The rapidity and the recentness with which the enlargement of the thyroid gland manifested itself tend to substantiate this view.

SUMMARY

A case of metastatic hypernephroma to the thyroid gland, the 16th proved case in the

literature, is reported. It is the first case observed in the records of the Massachusetts General Hospital. It is unusual in that the first sign of metastases occurred 9 years after a left nephrectomy for a hypernephroma and coincidental with the discovery of a similar tumor involving the right kidney.

MALFORMATION OF THE ANUS AND RECTUM

MILLARD S. ROSENBLATT, M.D., F.A.C.S., and ARTHUR MAY, M.D., Portland, Oregon

FROM December 1936 to December 1945, there were 20 patients with malformation of the anus and rectum admitted to Doernbecher Hospital. Of these, 11 were males and 9 were females. The incidence of all admissions for this period of time was 0.14 per cent.

The probable cause of this condition is some arrest or abnormality, which takes place in the 7th or 8th week of embryonic life. The details of these abnormalities and embryonic development have been clearly discussed by Ladd and Gross.

There are four distinct types of imperforate anus, ranging from simple stenosis to complete atresia of the anus and rectum. Figures 4a, 5b, 6a, and 7 are examples of these types.

The most common type in our series (as seen in Fig. 5b) was an absence of the anal opening in which the blind rectal pouch was only $\frac{1}{2}$ to 2 centimeters from the perineal dimple. We had 6 such cases in our series. These were most amenable to surgery and in every case good results were obtained.

In most of the cases in our series of complete absence of the rectum, where the rectal pouch was 2 to 3 centimeters from the perineal dimple, an associated rectovaginal fistula was present with a fistulous tract extending from the rectal pouch to the vagina near the posterior fourchette.

Seven of the 20 cases were of this type. In 5 of the 7 cases repair was made by dissecting away the fistulous tract and bringing the rectal pouch down to the anal dimple by cutting through the sphincter and making a new outlet. In 1 case repair was not made and in 1 other case a colostomy was necessary, then later, the rectal pouch was brought down to the anal dimple and the colostomy closed.

There were 2 cases of anal stenosis in which obstructive symptoms were outstanding and dilatation rather than surgery were the only procedures necessary (Figs. 6 and 6a).

One patient (L. W. No. 141451) had complete absence of the rectum—yet the perineal dimple had a deep indentation of approximately 2 centimeters (Fig. 4a). The rectal pouch was so far (3 centimeters) from the perineal dimple that the rectum could not be brought down and a colostomy had to be done. When the distance was 3 centimeters or over from the gas-filled rectum to the anal dimple, colostomies were done. There were 4 such cases in our series.

There are certain practical points to be stressed as a result of study of these cases.

The importance of determining in advance the distance between the perineum and the blind end of the bowel should be emphasized because the perineal dissection should not be persisted in, in cases in which the bowel is further than $2\frac{1}{2}$ centimeters from the perineum. The best method of determining this distance is described by Wangenstein and Rice. Anteroposterior and lateral x-ray films are taken with the baby in the upside down position with a metal marker in the anal dimple. If 8 hours have elapsed since birth, presence of gas in the rectal pouch will show the distance of the blind end of the bowel from the perineum. If the distance is less than $2\frac{1}{2}$ centimeters the bowel may be readily brought down to the perineum in most cases. If higher, perineal dissection may be attempted but if one is unsuccessful in finding the lower end of the bowel, the dissection should not be prolonged and colostomy should be done.

Any case of rectovaginal fistula or rectoperineal fistula can be brought down from below. This is not true of rectovesical or rectourethral fistulas—the fistula in these latter cases should be repaired later in life.

A noteworthy point is the frequent association of other congenital deformities with these deformities of the anus and rectum. The following table shows the different abnormalities encountered in these cases: cataracts, 2; strabismus, 1; rectovaginal fistula, 7; rectovesical fistula, 1; congenital heart, 3; atresia of esoph-

From the Department of Pediatrics and Surgery of the Doernbecher Hospital and University of Oregon Medical School.

agus, 1; hypospadias, 1; absence of radius, 1; absence of urethra, 1; undescended testis, 1; megalocolon, 1; double pelvis, 2; ectopic kidney, 1; hydroureter, 2; umbilical hernia, 1; absence of digits, 2; absence of external ear, 1. The only immediate postoperative death in this series was a child with absence of the urethra as well as the anus. Four other patients who died at dates ranging from 3 months to 2 years following surgery all had anomalies of the urinary tract.

The following are abstracts of the cases in our series.

CASE REPORTS

R. H., Case No. 138372, was born April 6, 1944, and admitted to Doernbecher Hospital April 7, 1944 for surgery. This child was born with an imperforate anus. On April 8, 1944 patient was taken to surgery. There was an unopened mucus-like channel (Fig. 1) running from the region of the imperforate anus to the base of the scrotum. This was tube-like in character, very narrow, and was filled with inspissated meconium. It was dissected up from the scrotum and an incision made at the anus in the anterior posterior direction and a large quantity of meconium was evacuated. Several other abnormalities were found in this child. Fingers were peculiar. There was a harsh systolic murmur at the apex. There was a small tumor on the external ear. The child was discharged on April 12, 1944. Now child has excellent sphincter control and is in good condition.

N. W., Case No. 123194, 3½ week old child, was admitted to the hospital on November 24, 1941 with a congenital absence of the anus and a rectovaginal fistula (Fig. 2). The fistula had apparently been sufficient for fecal outlet as the child had no history of obstruction and had been developing normally since birth. The mother had been cleaning the bowel out by catheterizing the fistulous tract. Physical examination revealed a well nourished child, whose only abnormality was of the perineum and genitalia. There was no anus present; just an anal dimple where the opening should be. There was a fistulous tract just inside the posterior fourchette which apparently communicated with the rectal pouch. Anteroposterior and lateral x-ray films of the pelvis, after injection of barium through a rectovaginal fistula by means of a rubber catheter, were taken. The rectum was well visualized, ending in a blind pouch, which is approximately 2 centimeters from the imperforate anus which is marked by small opaque marker. It was the opinion of the surgical staff that surgery should be deferred until a later date because of the mechanical difficulty involved in such a small child. Patient was discharged and the mother was instructed to keep the stools soft with mineral oil. Patient returned July 25, 1943, was taken to surgery where an incision was made through the anal dimple

and through the sphincter muscles up to the levator. Dissection was then carried around the rectum on each side and when this was complete the mucous membrane at the rectovaginal junction was incised and the entire anal rectal canal was transplanted to the perineum. The vaginal mucosa was repaired. The child made an uneventful recovery except for a retrovaginal defect which remained. The child's hospital stay was 15 days, being discharged on August 13, 1943. Further repair to be considered in the future. Later repair was done with satisfactory closure of the rectovaginal opening. Since this time patient has been asymptomatic.

K. P., Case No. 129015, 3 week old white female, entered Doernbecher Hospital January 4, 1943 with imperforate anus and a rectovaginal fistula (Fig. 2). The child was taken to surgery where the rectovaginal fistula was dissected and closed; and the distal end of the rectum was brought through the anal ring and the mucosa sewed to the skin. The rectal pouch was about 2 centimeters from the anal dimple. The child had a very stormy course postoperatively, but apparently recovered and had good sphincter control. However, on August 9, 1943 the child was admitted to the hospital with a terminal urinary tract infection. Autopsy showed bilateral hydroureters and hydronephrosis with a suppurative pyelonephritis.

D. E., Case No. 127337, 4 day old white male, entered the hospital on July 5, 1942 because of an imperforate anus. Examination revealed a well nourished white male infant. The abdomen was quite distended and taut. No hemia was detected. No abdominal mass was palpable. The anus was found to be imperforate. Remainder of the examination was essentially negative. X-ray examination revealed the heart and lungs normal. The abdomen revealed a large amount of free gas in the peritoneal cavity with the shadow of the small bowel containing air clearly visible (Fig. 3a). On August 7, 1942 the child was taken to surgery. The abdomen was opened whereby a large amount of air came through the incision. A large amount of yellowish material with fibrin flex was present in the abdomen. In the lower right quadrant of the abdomen there was a distended, necrotic portion of bowel. On examination this section of bowel revealed a small rupture through which much meconium has passed into the abdominal cavity. A rubber drain was passed beneath the bowel at this point and was delivered to the surface where it was exteriorized and the abdomen closed. The child showed a slow gradual improvement with a slow progressive weight gain. On August 7, 1942 barium meal was given. The esophagus, stomach, and duodenum were normal. Also the barium was injected in the distal loop of the colostomy. The roentgenographic findings were very suggestive of an occlusion or stenosis of the distal sigmoid approximately 4 centimeters above the anus (Fig. 3b). Inspection of the proximal loop of the colostomy revealed it to be sigmoid colon. At the time of discharge on August 24, 1942 the child

was showing a progressive weight increase, weighing 7 pounds 13½ ounces. His general condition was quite good. The child was readmitted on October 4, 1942. Since his discharge following surgery for imperforate anus he seemed quite well until 4 days before when he began to vomit. He had had no difficulty with the colostomy opening since his discharge. Physical examination at this time revealed a patent and functioning colostomy opening. The tissue around this area was redundant and inflamed. The child went rapidly downhill and died on October 10, 1942, 3 months after colostomy. Autopsy findings revealed: atresia of the lower rectum and anus; double-barrel colostomy, functioning, of the left lower quadrant; bilateral interstitial nephritis and left pyelitis and hydronephrosis.

D. H., Case No. 68466. This child entered the Doernbecher Hospital for the first time at the age of 3½ months. Since birth patient had had a rectovaginal fistula with imperforate anus (Fig. 2). The child returned for surgery at age of 4½ years. At the operation a rectovaginal fistula was dissected. The vaginal opening was closed and the rectal pouch brought to the anal dimple and the mucous membrane was sutured to the skin. The rectal pouch was 3 centimeters from the anal dimple. The child made an uneventful postoperative recovery and has had normal sphincter control. Dilatations were continued at home; the child has been seen in out patient clinic since 1941 and has had no further trouble.

A. J., Case No. 105727, 8½ hour old white male entered the Doernbecher Hospital with an imperforate anus. X-ray films were taken by the Wangenstein-Rice method and the rectum appeared to be 3 centimeters from the anal dimple (Fig. 4a). The child also had a hypospadias. Colostomy was done on January 13, 1940 and the child recovered uneventfully, yet, 1 month later the child returned to the hospital with a high fever and a methylene blue injection was given through the distal loop of the colostomy and it appeared in the urine in 2 hour proving the presence of a rectovesical fistula. The child was discharged and given a poor prognosis. Surgery was impossible due to the child's poor condition at this time. The child was followed for 1 year in the out patient clinic with no improvement of the pyelitis which he contracted shortly after the second hospital admission. The child did not return and further prognosis of the case is not known.

S. K., Case No. 141466, 7 day old white female entered the Doernbecher Hospital on October 9, 1944, one of twins, with only a dimple at the anus. The child had an opening between the vagina and the anus (Fig. 2). A repair of the imperforate anus was done; the rectovaginal fistula was dissected out and removed and the mucous membrane was sutured to the skin at the anal dimple forming an anal orifice. The rectal pouch was approximately 2½ centimeters from the anal dimple. The child made an excellent recovery and was discharged on October 30, 1944. Since this time the child has been asymptomatic with good sphincter control.

Fig. 1. Unopened channel running from the anal dimple to the base of the scrotum. This was filled with inspissated meconium.

L. H., Case No. 112704, 1 day old white male was brought in with an imperforate anus. X-ray films on admission showed the air column in the rectum to be within 1½ centimeters of the anal dimple (Fig. 5 and 5a). The child was taken to surgery where the rectal pouch was opened from a perineal incision. A large amount of meconium was expressed. The cutaneous margin of the rectal pouch was unable to be sutured completely to the anal opening and a rubber tube was inserted. This was kept dilated daily and thus a normal opening was established and the child was discharged and has remained asymptomatic.

B. M. C., Case No. 106007, 3 day old white female entered Doernbecher Hospital on January 17, 1945

Fig. 2. Drawing of the rectovaginal fistula, which was present in 7 cases of our series.

Fig. 3. a, Showing pneumoperitoneum in case of imperforate anus

with a rectovaginal fistula and absence of anus (Fig. 2). Distance from rectal pouch to the anal dimple is unknown. The child was not treated at this time for the imperforate anus and was discharged. The child also had atresia of the esophagus, incomplete.

D. A. F., Case No. 91697, 3 day old white male entered Doernbecher Hospital on September 19, 1938 with an imperforate anus. X ray films revealed a gas bubble to be just skin thickness from the rectum (Fig. 5a). The child was taken to surgery where the skin overlying the anal dimple was opened and the rectum was opened. A large amount of meconium was released. The anus and rectum were dilated twice daily. The child made an uneventful recovery and was sent home. The mother was instructed to dilate the anus daily for 6 months. The child has had no complications since.

R. G., Case No. 123004. This child had an imperforate anus at birth on May 8, 1938. On May 9, 1938 a colostomy was performed. The child had apparently carried on a normal activity at that time until the admission on November 15, 1941, at which time x-ray films of the pelvis were taken after injection of lipiodol through a distal colostomy loop with an opaque marker pressed against the anus which was imperforate. The distal rectum was absent and there was a distance of 4 centimeters from the opaque

Fig. 3. b, Injection of colostomy with barium—no filling below the sigmoid

marker to that portion of the rectum which was filled (Figs. 4 and 4a). At the operation an anterior posterior incision was made in the midline of the perineal floor, extending from the scrotum backward almost to the tip of the coccyx. The anal sphincter muscles were partially split in order to give adequate exposure, and it was necessary to bisect the perineal body in order to reach the rectal pouch. The latter was located about 3 to 4 centimeters above the anal dimple. The pouch was then carefully freed from adjacent tissues and structures. The rectal wall was then fixed to the subcutaneous tissue with interrupted cotton stitches after the pouch was freed sufficiently to allow it to be brought to the perineum without tension. The pouch was opened into and the lumen demonstrated by the presence of the rectal tube which had been placed in the colostomy before surgery. The lining of the pouch was then sutured to the skin of the perineum, leaving an opening which was sufficiently large to easily admit the big index finger. Then a side-to-side anastomosis of the two loops of colon was done. The abdomen was then closed in layers around the colostomy. In attempting to dissect the dense adhesions free from the colostomy the bladder was inadvertently opened into, but im-

Fig. 4. X-ray film with lipiodol injected into the distal colostomy loop showing end of bowel a great distance from perineum.

mediately closed. After surgery a retention catheter was left in place. Colostomy was closed on April 1, 1942. After surgery child made an uneventful recovery. During the last 2 years he has had fair bowel movement with fair sphincter control. The anus has been dilated at intervals.

L. B., Case No. 146510, 2 day old white female, was admitted to the Doernbecher Hospital on July 7, 1945 with the chief complaint of imperforate anus. The patient vomited mucus 1 hour after birth and has vomited all offerings by mouth. Upon attempting a rectal, the nurse discovered the anus to be closed. No other congenital abnormalities were noticed. Anteroposterior and lateral x-ray films were taken (Figs. 5a and 5b), and showed air outlining the rectum which extends down to within about 1 centimeter of the dimple of the anus. In the lateral film the direction of the rectum is normal, the blind end extending posteriorly. The pouch is broad with smooth borders. Patient was taken to surgery at 3:00 p.m. on July 7, 1945. Under ether anesthesia the imperforate anus was repaired. The septum which was between the rectum and the anus was divided and the mucus membrane of the rectum was sutured to the mucus membrane just internal to the sphincter. Patient passed considerable gas and meconium and was returned to the ward in good con-

Fig. 4. a, Drawing of the defect shown in x-ray film in Figure 4.

dition. Patient was discharged July 15, 1945 asymptomatic. The anal outlet was to be dilated by home physician to keep the opening adequate. The patient has been asymptomatic since.

A. P., Case No. 140517, 16 month old white male entered the Doernbecher Hospital on August 11, 1944 for his first admission. He was treated at this time for chronic sinusitis and a kidney infection. He had had an operation for an imperforate anus at the age of 4 days (Fig. 5a). On the present examination the child has an extremely small stenotic anus which will not admit the tip of the little finger. The patient also had a megacolon from obstruction from massing of feces in the colon. Cystograms and intravenous pyelograms disclosed two kidneys on the left side. One is normal and one showed a marked nephrosis and hydronephrosis. The child gave the impression of having renal rickets and renal dwarfism, with a low blood calcium of 7 milligrams per cent. On August 22, 1944 the child had a manual dilatation of the rectum and the large bowel was cleaned out. He was discharged August 23, 1944. On September 25, 1945 the child was readmitted to the hospital—dead on arrival. Autopsy revealed extensive bronchopneumonia; agenesis of the right kidney; double left pelvis and ureters with hydronephrosis and megaloureter; megalocolon; undescended left testis.

T. T., Case No. 149691, 4 month old white male entered the Doernbecher Hospital on August 21, 1945 with the chief complaint of constipation and vomiting. Patient was well until 4 days previous to admission when he became very irritable, did not have any bowel movements and vomited several times. The physical examination was essentially negative except for a distended abdomen which had visible peristalsis and tympany. The rectal sphincter was very tiny. It would not admit the finger. Otherwise, the physical was essentially negative. Hematology, tuberculin, and serology were negative. Barium enema revealed a large redundant sigmoid with anal stenosis (Figs. 6 and 6a). The child was given daily anal dilatations which resulted in relief

of distension and partial obstruction. Follow-up care showed no further bowel obstruction and after

Fig. 5a.

several months of anal dilatation, he had had no more symptoms.

L. W., Case No. 141451, 6 day old male infant entered Doernbecher Hospital on October 7, 1945 for relief of imperforate anus, also for a deformity of the right forearm and genitalia. Physical examination revealed an enlarged heart with soft, systolic murmur heard at the apex. Imperforate urethra, atresia of the anus, absence of the right radius and right first metacarpal. X-ray films were taken showing an area about 3 centimeters from the air filled rectum to the perineal dimple. Child was taken to surgery on October 8, 1945 where an attempt was made to bring the rectum down to the perineum. The rectum was not found but the bladder was exposed, opened, and the edges sutured to the anal opening. Due to the distance of 3 centimeters from the perineal dimple to the abdominal cavity, the bowel could not be brought down, so a left rectus incision was made into the peritoneal cavity. The sigmoid colon was exteriorized and a double-barrel colostomy was established. No external urethral opening could be found. The colostomy was opened and a small amount of meconium came out. The bladder was brought down because of possible contamination with colostomy, suprapubic drainage was contraindicated. The child did not respond well after surgery and expired.

P. A. R., Case No. 117417, 6 week old white female, entered Doernbecher Hospital on March 7, 1941 with a stenosis of the anal opening (Fig. 6a). The rectum was dilated and the dilatations were continued for several months after which the child remained asymptomatic.

M. F. H., Case No. 77635, 4 hour old white female entered Doernbecher Hospital on July 26, 1939 with an imperforate anus and a rectovaginal fistula since birth. A barium enema was given through the rectovaginal fistula showing a greatly dilated rectum. The rectum was found to be 3 centimeters from the anal dimple. A colostomy was done at this time. On June 10, 1940 a repair of the rectovaginal fistula was done. The fistulous tract was excised and the rectum was brought out to the anal dimple and the mucous membrane was sutured to the skin. Permanent colostomy was not made since the child had a fairly adequate anal opening with sphincter control. The child did not come in for follow-up care.

A. D. P., Case No. 95440, 1 day old child, was admitted to the Doernbecher Hospital on January 15, 1939 with the chief complaint of imperforate anus. He was a full term, well developed baby weighing 10 pounds. There was a small sinus tract which appeared to be filled with meconium extending out from the anal dimple. By pressure over this area meconium passed back into the rectum. On January 16, 1939 a small incision was made in this tract and a probe passed through it into the rectum. The tract was dilated gently with a hemostat. A large amount of meconium was expelled. This tract was dilated gently every day to keep the anal ring open. There was good sphincter tone present. It functioned fairly well until 1 year of age at which time the child was again admitted to the hospital complaining of abdominal pain and vomiting. At this time the child was well developed and well nourished. The anus was very small, partially admitting the tip of the little finger. The rectum was filled with fecal material. The child was taken to surgery at this time and the sphincter ani was dilated under ether anesthesia. A large amount of dry fecal material was removed. The child's rectum was dilated daily up to a No. 32 French catheter. Since this time the child has been fairly well.

R. E. K., Case No. 102290, 3½ month old white female, entered the Doernbecher Hospital on September 6, 1939 for surgical correction of an imperforate anus. The child has been having fairly regular bowel movements through a rectovaginal fistula (Fig. 2). The child has never vomited and seems to be in every other way a normal child. Physical examination revealed a well nourished, well developed girl. No anus is present, but a small dimple can be seen on the perineum. Urinalysis revealed a three plus pus. Hematology showed an 86 per cent hemoglobin and 17,000 white blood count. A new rectal outlet was created to correct the imperforate anus. The rectal pouch was 3 centimeters from the perineal dimple. The rectovaginal fistula was not closed at this time. The child was discharged asymptomatic.

The early recognition of these malformations, especially those with complete obstruction, is important. Inspection at the time of the delivery will reveal almost all the abnormalities, except the defect such as in Figure 7. In this type of case the external opening ap-

Fig. 7. Drawing showing pathology in patient who appeared to have normal rectal opening

appears normal and the rectal temperature can be taken, but no meconium passes.

The operative details in these cases are as follows: The child is placed in the prone position, with the hips elevated, and an incision is made in the midline in the region of the anal dimple in the anterior-posterior direction. The external sphincter is thus divided in the midline and its function not destroyed. The external sphincter is usually present in these cases, inasmuch as its mesenchymal origin, embryologically, is different from that of the rectum itself. Thus anal control is usually good. When the bowel is any distance from the perineum, it is freed by dissection sufficiently to bring it down and suture it to the skin between the lateral halves of the sphincter muscle, with closure of the skin anteriorly and posteriorly to the rectum.

In the cases of rectovaginal fistula, it is easy to make the mistake of not bringing the rectum far enough posteriorly. In these cases the area of the rectum, where the fistula exists, is best brought to the outside, or otherwise, the fistula may recur. In all of these cases tension must not be present in suturing.

The cases of rectovesical fistula and rectourethral fistula must not be repaired until the child has attained some growth.

The postoperative care of the rectal opening depends upon careful, gentle dilatation with a bivalve nasal type speculum. This should be kept up at occasional intervals until the anus admits the examining finger. Some of the cases that require colostomy may later have the bowel brought to the perineum and the colostomy closed. Our case, No. 123004, was so treated. A rectal tube was placed in the distal colostomy opening and helped identify the lower end of the bowel at the time of the perineal dissection. After closure of the colostomy, the child had good bowel control.

SUMMARY

1. Twenty cases of malformation of the anus and rectum have been reviewed.
2. Important points in their recognition, study, and treatment are discussed.

THE MANAGEMENT OF OSTEOMYELITIS SECONDARY TO WAR WOUNDS

K. ARMAND FISCHER, B.S., M.D., F.A.C.S., Louisville, Kentucky

THE occurrence of long existing suppurating wounds associated with compound fractures has been one of the most important problems encountered by the military orthopedic surgeon. The circumstances under which soldiers receive wounds, that is, with dirty clothing in place, fragments of land mines carrying infected soil into wounds, shell bursts which plow up the ground and then reach the limb, and the delay in getting surgical care, all go to make a great number of infected fractures during a war. In spite of the hazards of military wounds, however, it has been surprising to see the number of limbs which healed quickly when early medical care was given. The majority of the compound fractures treated by the temporary open wound method healed in the same period that a closed fracture would unite in civil life.

TYPES OF CASES

The usual compound fracture patient who was received in a general hospital from overseas had a well fitting cast with the fracture in good position and alignment. If there was a foul odor to the cast, the plaster was changed soon after admission to the hospital because every man wanted a furlough or leave as soon as possible. Usually the wounds at that time were mere granulating areas which needed silver nitrate cauterization, a skin graft, or sometimes the patient had already undergone a secondary closure. In other cases bone was exposed in the wound and frequently loose sequestra could be lifted out. This type of patient showed no sign of sepsis and his general health was good. His blood count, hemoglobin, and hematocrit readings were normal. His state of nutrition was good, and he needed very little treatment other than cast immobilization until sufficient healing of the bone had occurred. Practically every one of these patients was started on some therapeutic exercise

to the injured limb even while in the cast, moving the neighboring joints or muscles underneath the cast. At times, in other cases, there was so much drainage from unhealthy soft tissue wounds that the surrounding skin was in bad condition from the presence of the secretions. These later suppurating wounds were treated in whirlpool baths for a period if the bones were in a condition to allow a minimum of immobilization. These warm water baths helped to clean up the wounds and skin very quickly.

Another group of patients had unhealed or healing fractures with suppurating wounds with a definite bone infection as shown by x-ray examination. In some sequestra, shell fragments, and débris were present; in others good drainage was lacking. The majority of these patients showed very little, if any, systemic changes due to the bone infection. Their nutritional state was excellent and their blood count, hemoglobin, and blood volume were normal. These patients usually needed surgical treatment and an attempt was made to eliminate the infected areas in from 3 to 4 months following injury. In some instances the removal of a sequestrum or foreign body resulted in permanent healing of the wound; in others dead bone was found attached to callus because surgery had been inadequate to insure continuous drainage of small or large spicules of bone and dead tissue.

Another group of patients who had had severely traumatized extremities with long existing suppurating wounds, showed marked evidence of the systemic effects of chronic sepsis. This type of patient was more difficult to treat, and it took a much longer time for healing to occur. These patients had very little immunity to their infection and were in an extensively depleted state.

The septic and depleted patient was in no condition to withstand surgical drainage, removal of foreign bodies and dead bone, or

of penicillin together with sulfadiazine were started 4 days before surgery and were continued after surgery for 4 to 5 days and little, if any, reaction followed.

After 4 to 7 days' preparation, a compound fracture with osteomyelitis was usually ready for some type of surgery. At operation a pneumatic tourniquet was used when possible, and it has proved to be a very valuable adjunct to this type of surgery of the arm, forearm, and below the upper one-third of the femur. The blood was expressed from the extremity with elastic bandages or by elevation previous to the application of the tourniquet. The advantages of a dry field for this type of surgery are that one could see the diseased areas of bone more clearly and furthermore the amount of blood lost was kept at a minimum.

At the time of surgery the draining sinuses were opened widely down to the infected fracture. All loose and dead fragments of bone, metallic fragments, and debris were removed. A generous saucerization of the bone was done. The scarred and avascular tissues were excised from the wound. Then the wound was flushed with normal saline to remove any small bone and soft tissue debris. Then moistened muslin or nylon strips which were close meshed were used to line the depths and sides of the wound, and mechanics' waste or gauze was packed on top of the muslin with gentle firm pressure. All patients were immobilized in plaster or traction. Postoperative oozing was controlled by elevation of the part, and if the pack had been placed correctly, there was usually a minimum of bleeding. In extensive saucerizations, the patient frequently needed a transfusion during or after surgery, depending on the amount of blood lost. From 200,000 to 500,000 units of penicillin were given in 2000 cubic centimeters of saline in the first 24 hours after operation. After that period the drug was given intramuscularly at 3 hour intervals in 25,000 unit doses during the day. Sulfadiazine was started after surgery as soon as the patient could tolerate it by mouth. As soon as possible, these patients were placed on the high protein, high caloric, and high vitamin diets.

Several days following surgery a blood count, hemoglobin, and other laboratory anal-

yses were made to determine the patient's reaction to the surgery. Transfusions were given as often as was necessary to make the red blood count and hemoglobin of these patients approach the normal in order to build up their resistance and immunity to infections.

Following saucerization surgery, the wounds were treated by one of several methods. The procedure that was used most extensively was the application of a split thickness skin graft. On the sixth or seventh day following the initial surgery, the cast was removed, and the wound packing was taken out. Cultures were made from the wounds for study. At this time, there were usually fine healthy granulations present with a clean appearance of all the tissues. If, however, the wound appeared dirty with some necrotic tissue showing, and definite areas of pus present, then further surgical and possible chemical treatment of the wound was necessary to make it receptive for a skin covering. Otherwise on the following day, the packing was removed, and a split thickness skin graft was taken with a Padgett hood dermatome and applied to the depths and sides of the wound. The grafts measured from .014 to .018 inch, the thinner grafts being used in the least favorable recipient sites. Before applying the skin, the saucerized defect was prepared by freshening the surface of the wound with a scalpel or gauze, removing any necrotic tissue, slough, or blood clot. Then the defect was irrigated thoroughly with saline and packed with warm moist gauze until the skin was applied. The skin was tailored to fit the defect without tension, and the graft was sutured to the wound edges with interrupted silk stitches. The grafts were perforated in several areas to allow the escape of excess secretions. A layer of boric acid ointment gauze was applied over the skin, and gauze packing or mechanics' waste was inserted in the defect on top of the skin. Dry dressings were placed on top of the packing, and an ace bandage was used to maintain an even firm pressure in the wound. Plaster splints were applied to the extremity, and the limb was elevated on returning to bed. Penicillin and sulfadiazine which were begun before the saucerization were continued after skin grafting for 5 to 7 days. At the end of a

week, the wound packing and boric ointment gauze were removed, and the graft was exposed to the air. A heat lamp was applied two or three times a day for 15 to 20 minutes if the graft was moist.

Another type of wound treatment following saucerizations that proved to be a very valuable procedure was the method of secondary closure. When the wound edges were not separated widely, and there had been only a minimum of soft tissue loss, these conditions seemed to be ideal for a delayed closure. If one expected to use this method following saucerization, the wound was packed similarly to that mentioned before the skin grafting procedure. Seven to 10 days later, the packing was removed, and the wound inspected. If it was clean, then a moist pack was inserted, and the patient was made ready for surgery on the following day. At surgery, the skin edges were excised, and the soft tissues were loosened up enough to approximate the skin and subcutaneous tissues. After a thorough cleansing of the wound with saline, the skin and subcutaneous tissues were closed with through-and-through stitches, avoiding if possible the use of buried sutures. If any dead space remained, a soft rubber drain was inserted for several days. In case the wound looked grossly infected and dirty, treatment with irrigations and penicillin packs was carried out for a time before closure was attempted.

Another method of delayed closure used successfully in superficial saucerizations was the shifting of a lateral flap of skin and subcutaneous tissue over the wound and the suturing of the edges. The bare wound left after the flap was moved was covered with a split thickness skin graft where needed.

Treatment of osteomyelitis secondary to war wounds by primary closure was carried out in a number of instances at the time of saucerization. Frequently when there were foreign bodies in infected bone, infections of the ilium and other pelvic bones, and cases of insidious drainage with sequestra present, primary closure proved to be an ideal treatment. At times a flap of skin and subcutaneous tissue was shifted over the saucerized area, as mentioned under secondary closure, and a

split thickness graft placed over the denuded area.

ANALYSIS OF RESULTS

An analysis of the results of wound treatment following saucerization surgery by skin grafting, secondary closure, and primary closure has been made. No case was considered successful unless the wound had been healed for at least 3 months. The results with the skin grafting type of treatment have been most satisfactory. A recent survey of 264 cases revealed a complete healing of 25 per cent of the wounds in 30 days. At the end of 60 days, another 50 per cent of the cases had healed, leaving 25 per cent unhealed. Of this latter group only 6 per cent were complete failures. The remaining patients needed a partial resaucerization and skin graft. The failures of this method have been judged to be due to a poor blood supply to the tissues under the graft, a lack of maintenance of firm even pressure by the dressing after skin graft surgery, and lastly due to infected tissues under the graft and incomplete saucerization surgery. The skin graft method has been very popular with the patients in military hospitals because it created a closed wound from a dirty infected one in a short period, eliminating the dressings, odors, and inconveniences of some other methods. Since the soft tissue wounds healed quickly with this method, the bones likewise healed rapidly when they received a skin covering. However this treatment did not eliminate altogether the need for further surgery in all the cases. Many deep and wide wounds having a thin skin covering needed good skin flaps with fatty subcutaneous tissues when further bone surgery was planned to keep the wounds from breaking down with usage, and in others for cosmetic reasons. These patients were usually given a trial of 3 months hard usage on the extremities if the bones had healed. At the end of that period if the skin wounds had not broken down, then the patient did not need to undergo further surgery unless he wanted it for cosmetic reasons.

The results of delayed closure were very encouraging, the wounds showing some drainage in 9 instances out of 42 cases which were

followed. A number of these wounds closed spontaneously after a few weeks' drainage. The secondary closures in which a drain was inserted at the time of surgery because of a dead space, usually closed spontaneously in the majority of instances within 7 to 10 days following removal of the drain. The failures in this group of cases were attributed to incomplete surgery and the leaving of a dead space where tissue fluids collected.

Primary closure was used in 46 patients, and wound drainage following surgery occurred in 10 instances. This low percentage of reinfection could probably be accounted for by the proper selection of cases for the use of an immediate closure.

SUMMARY AND CONCLUSIONS

The management of osteomyelitis secondary to war wounds has not been a problem of curative surgery alone. At times intensive constitutional treatment was necessary to alleviate the attendant anemia, hypoproteinemia, and disturbed fluid balance in the septic and depleted patient.

Frequently the patient was in a low mental state.

Five methods of wound treatment following sequestrectomy and saucerization were used. This study has revealed that delayed closure, primary closure, and skin grafting were very useful procedures in creating an early closed wound from an open infected one.

THE SURGICAL TREATMENT OF GANGRENE IN TRENCH FOOT

HARRIS B. SHUMACKER, Jr., M.D., Lieutenant Colonel, M.C., A.U.S., Baltimore, Maryland

THOUGH gangrene in trench foot has similarities to gangrene in other vascular disorders, it presents certain problems which are peculiar to this condition. Distinguishing features are the high incidence of infection, the occurrence of either superficial or deep gangrene of limited or considerable extent, the lack of pain due to the gangrene itself or the resulting ulceration, the common association of intense vasospasm, and the absence of any extensive arterial obliteration in the foot proximal to the area of gangrene.

Trench foot gangrene differs from the gangrene of thromboangiitis obliterans, arteriosclerosis, and other obliterative diseases chiefly because of the general absence in trench foot of the reduction in the circulation of the foot from obliterative arterial changes so regularly present in these diseases. Conversely, whereas relatively normal circulation rarely prevails in the obliterative disorders upon elimination of vasoconstrictor impulses, relatively normal circulation does generally prevail in the case of trench foot. Trench foot gangrene further differs from the disorders named in the general lack of any severe rest pain even when open ulcers are present. Initially there may be very distressing rest pain in patients who have trench foot, whether gangrene is present or not, but after an interval of some weeks or months the majority of patients have little or no pain at rest. Though infection sometimes complicates gangrene in the obliterative diseases, it is much more commonly present in trench foot with deep gangrene. Skin defects can rarely be covered by grafts in the former but can often be repaired in this manner in trench foot.

In Raynaud's disease and like disorders the ulcerations and gangrene are generally superficial and limited in extent. In trench foot the

gangrene may be superficial or deep, limited or extensive. The gangrene of trench foot is closely allied to that which follows frostbite and immersion foot. All of these disorders are alike in that obliterative arterial changes are largely limited to the areas of gangrene and perhaps to areas immediately proximal to these. Patients with frostbite and disorders resembling Raynaud's disease tend to have few symptoms associated with gangrene other than cold sensitivity and hyperhidrosis which are very common in the former and the rule in the latter. In trench foot and in immersion foot, on the other hand, there are generally associated symptoms consequent to damage of nerves and muscles in the foot proximal to the area of gangrene. Areas of hypesthesia or hyperesthesia, atrophy of muscle, and contractures are relatively common in trench foot, and almost all patients have pain on weight bearing. These symptoms are prevalent in trench foot without gangrene and are not due to postural difficulties resulting from the ischemic loss of tissue. Hyperhidrosis, coldness, and cyanosis are commonly present.

It is the purpose of this communication to discuss certain problems which have arisen in the care of patients with gangrene from trench foot and to describe the manner in which they have been handled.

THE PROBLEM OF INFECTION

Infection was very commonly associated with the gangrene of trench foot. Infection was often minimal in instances of superficial gangrene but presented a serious problem in cases with deep gangrene, almost all of which had extensive infection. The circumstances in which trench foot is incurred all favor the introduction of infection. In the first place, the hygiene of the feet is necessarily often neglected under conditions of combat. At the time of exposure the patient has generally been unable to change his wet shoes and socks

From the Vascular Center, Mayo General Hospital, Galesburg, Illinois.

for a period of days or weeks. In addition to the tendency for skin maceration and bleb formation which appears to be the direct result of ischemia resulting from the exposure, the continual wetness of the feet and the edema further favor maceration of the skin. The blebs, skin desquamation, and loss of nails, which occur so commonly, serve as portals of entry for pathogenic organisms. Not infrequently the blebs on the digits are undergoing gangrenous changes.

When the patients are first seen as they are returned to the Zone of the Interior the gangrenous parts often are partially separated at the line of demarcation and this area is generally bathed in foul smelling pus. Sometimes there is evidence of extensive infection throughout the gangrenous portions. Not infrequently where the gangrene appears to be "dry," one finds on removal of this tissue through the line of demarcation that the gangrenous part is simply covering a pool of pus. The infection is invariably a mixed one and very commonly penicillin and sulfonamide-resistant *Bacillus proteus* and *Bacillus pyocyaneus* are present in addition to susceptible organisms.

Most of the patients were treated either with sulfadiazine or with penicillin. All of them were treated with sterile warm saline compresses. The gangrenous parts were excised or amputated through the line of demarcation. After this procedure was carried out there was a marked improvement in the infection. In no instance was there spread of infection to adjacent soft tissues. Osteomyelitis in the proximal stump, however, was often present and not infrequently required sequestrectomy, revision of stumps or other measures. The presence of infection handicapped treatment by precluding in most instances the primary closure of amputation stumps. Although the infection cleared grossly under treatment, it persisted in sufficient degree to offer some handicap to the success of split thickness and other skin grafts.

Of the measures instituted in order to control infection, it is felt that removal of the gangrenous parts and the use of warm sterile saline compresses were most efficacious. Not infrequently it was necessary to protect the

intact skin with some ointment such as zinc oxide in order to prevent maceration during the period compresses were in use. This tendency to skin maceration seemed to have been greater than in normal limbs. It may have been due in part to the fact that large areas of skin were often only recently epithelized following extensive desquamation. It may have been due in part to the excessive hyperhidrosis which many patients had. With regard to sulfadiazine or penicillin it is felt that these drugs may have had some effect in preventing spreading of infection. If they had any beneficial effect upon the local infection itself this was not apparent. Use of aqueous mercurochrome locally proved more successful in clearing *Bacillus pyocyaneus* infection than dilute acetic acid. Unfortunately streptomycin was not available. From my small later experience with this drug in other infections in gangrenous stumps, it is believed that it might have been very useful.

A number of instances of apparently "dry" superficial gangrene have been seen in which there was present under the crust an active infection which led to osteomyelitis. In such cases amputation was often necessary. Because of this occurrence, it is my opinion that when areas of superficial gangrene fail to separate promptly they should be compressed in an effort to hasten separation of the gangrenous tissue, and epithelization.

THE PROBLEM OF VASOCONSTRICTION

Elsewhere (2) the problem of vasoconstriction in trench foot with gangrene has been discussed and the utility of lumbar sympathetic ganglionectomy in correcting this disorder has been described. It is sufficient to say that the majority of patients with deep gangrene presented evidence of rather marked vasoconstriction. The feet were frequently cold, cyanotic, and sweated profusely. In some cases the occurrence of vasoconstriction was masked by the infection and the local heat associated with the inflammatory reaction. In such cases cooling of the feet was observed as the infection cleared. In a few patients the feet were not only warm but had almost complete absence of sweating. Such cases were relatively few.

Fig. 1. Photographs of feet of patients with gangrene which healed following sympathectomy and excision of the gangrenous parts without further surgery. In the 3 cases illustrated the gangrene was deep and extended down to the bony structures. Patient whose feet are shown in a, upper left, also had an area of gangrene on the sole of the foot which healed after sympathectomy. Patients in b, upper right, had unilateral and patient in c, at left, had bilateral sympathectomy.

Although eventual healing can generally be obtained without sympathectomy, it is felt that this procedure has been most useful in bringing about prompt healing and in limiting the amount of tissue loss (Figs. 1 to 5). Thirty-eight lumbar sympathectomies were performed in 30 patients with deep gangrene. Satisfactory and fairly prompt healing occurred in all. Where small split grafts were attempted there was often difficulty in securing takes, but tube transfer grafts were as successfully transferred as to normal limbs.

It was often striking how rapidly epithelization took place following sympathectomy. The contrast of this rapid epithelization to the former slow healing was especially evident in those cases in which sympathectomy had been performed in the presence of marked vasospasm. After operation the feet were warm, of good color, dry. The dryness was readily controlled with a daily application of lanolin.

In 17 patients with trench foot following unilateral sympathectomy, skin temperatures of the toes or stumps averaged 25.8 degrees C,

Fig. 2. Photographs of feet with gangrene, showing healing after sympathectomy and revision of stumps. A unilateral sympathectomy was done in patient in a, lateral in patient in b. The gangrenous part was excised in patient a at the time of sympathectomy. Three and one-half weeks later a split graft was applied to the ulcer

but this failed to take. Three weeks later the distal phalanx was amputated, the stump revised, and sutured. Patient, whose feet are shown in b, had initially excision of the gangrenous parts and a bilateral sympathectomy. At left, b, is illustrated the condition following this procedure. This patient demonstrates the difficulty resulting from infection. A split graft applied to the left great toe failed to heal. Both great toes required revision because of osteomyelitis and the right 5th toe was amputated because of osteomyelitis.

Fig. 3. Photographs of 4 patients with gangrene in which split thickness grafts were of considerable aid in obtaining a good healing with minimal loss of tissue. Unilateral sympathectomy was done in patients shown in a, b, c, and bilateral in patient in d. Split thickness grafts were uti-

lized in covering the stumps of the 1st, 3rd, and 4th toes in a, the ulcer over the end of the metatarsals in b, the defect along the dorsomesial aspect of the toe in c, and the ulcers over the stumps of both 1st toes in d. A good functional result was obtained in all cases.

in the untreated limb and 33.2 degrees C, in the sympathectomized limb. Oscillometry at the ankle averaged 2.6 on the untreated side and 4.6 on the side operated upon. In general,

the dorsal pedal and posterior tibial pulses were present and full, and there was no evidence to suggest any extensive obliterative change in the arteries of the foot. It is very

Fig. 4. Photographs of feet of 2 patients in whom tube transfer grafts were utilized. b, left, represents the condition on admission, a, left, and b, right, the condition following amputation and a, right, and c, left and right, the final result. Both patients walked surprisingly well and with little discomfort. Sympathectomy was done in both patients.

Fig. 5. Photographs of feet in which tube transfer grafts were utilized. *a*, left, represents the condition on admission and *a*, right, the final result. In this case both 4th and 5th toes were preserved but were subsequently amputated because of stiffness and discomfort. *b*, left and right, shows the condition following amputation in another case. The heads of the metatarsals are exposed. *c*, left and right, shows the final result after transfer of full thickness skin to both feet by means of a tube graft. Both patients had bilateral lumbar sympathectomy. A good functional result was obtained in both cases.

probably true that there may be thrombosis of the digital artery or small branches in the stumps adjacent to the line of demarcation.

THE PROBLEM OF AMPUTATION

Because of the prevalence of marked infection, closed amputations were rarely possible. Generally the gangrenous plaques and the

gangrenous digits were amputated through the line of demarcation shortly after admission. If sympathectomy was performed, amputation was carried out at this time. Protruding stumps of bone were often left because the infection made it inadvisable to carry out a complete revision. Subsequently the stumps were revised, rongeur away the protruding

Fig. 6. Photograph of patients who had extensive gangrene. In patient *a*, both feet were entirely gangrenous, and leg amputation was necessary. Patient in *b* had undergone prior to admission an amputation which was partially tarsal-metatarsal and partially through the proximal metatarsal area. The stump was painful and entirely unsatisfactory. He was transferred to an amputation center for a Syme's revision. *c*, Shows the end-result in a patient who had lost all toes and in whom healing occurred after sympathectomy. Because of the thin adherent skin over the stump, this was revised by sacrificing most of the head of the 1st and 2nd metatarsals. Though the stump was satisfactory it was felt that a more useful stump would have been obtained had a tube transfer graft been used instead of reamputation.

Fig 7 Photographs showing the tube used in transferring skin, a, and the method of mobilization, b, and c.

phalanges. In many instances disarticulation was performed. No difficulty was encountered from disarticulation, and osteomyelitis in the stump was less common following this procedure than following amputation through phalanges. Every effort was made to avoid traumatizing the stump at operation and all the tissue possible was conserved. I feel that this policy of conservatism gave good results.

The extent of gangrene varied. In some patients a single toe was gangrenous and in others gangrene involved all the toes. In some the gangrene was limited to the distal or the distal and mid phalanges. In others the toes were completely gangrenous. In 13 extremities the gangrene was sufficiently extensive so that following amputation the heads of metatarsals were left exposed and in 7 it was necessary to remove portions of the metatarsals. Frequently in such cases it was necessary to cover the defect with full thickness skin by transfer graft. Where only a portion of the heads of metatarsals had to be sacrificed, useful feet were obtained. Only in 2 cases was foot or leg amputation necessary. One was a patient who had gangrene of both feet (Fig. 6a). He was transferred to an amputation center for a leg amputation. Another patient had undergone an amputation, partially tarsal-metatarsal, partially through the proximal portion of the metatarsals (Fig. 6b). His stump was painful, unstable, and entirely unsatisfactory. He was transferred to an amputation center for a Symes revision.

THE PROBLEM OF SKIN GRAFTS AND PLASTIC REVISION

In most patients skin grafting was unnecessary (Fig. 1). Where amputation was carried out through the phalanges, epithelization generally occurred promptly. In most of them the new skin was good enough to withstand the trauma of walking without difficulty. In a few instances a thin skin was adherent to bone and in these cases revision with primary closure could be performed. When a large defect occurred, particularly in instances where the entire toe or toes had been lost, it was desirable to cover the defect with a split thickness graft to serve as a temporary dressing even should full thickness skin subsequently have to be transferred. In general, split thickness grafts had a high instance of failures. It was apparent that this difficulty resulted from infection rather than from poor circulation in the stump. Occasional split thickness grafts were entirely satisfactory in covering defects (Fig. 3).

In 5 cases it was necessary to utilize tube grafts (Figs. 4, 5, and 7). In all of these cases the metatarsal heads were exposed. Fortunately, the skin of the sole was generally intact so that the graft would largely be on a non-weight bearing surface. When the first patient was operated upon it was my plan to elevate a double pedicle graft or tube from the opposite leg, to place beneath it a split thickness graft, and subsequently to transfer it to the defect of the foot. I was surprised to find

at operation that sufficient atrophy had taken place to permit primary closure of the skin beneath the pedicle. Primary closure was done, and the pedicle was converted into a tube. Three weeks later the tube was divided at its lower end and sutured to the defect of the foot, the limbs being held in place with plaster of Paris. In the other 4 cases in which transfer grafts were necessary it was found possible to utilize the same procedure.

The technique involved was as follows: Two parallel incisions were made on the posteromedial aspect of the contralateral leg. The width and length of the pedicle were determined by the size of the ulcer to be covered. The anterior incision was placed just posterior to the saphenous vein, and care was taken to avoid injury to the saphenous nerve. The skin between the 2 incisions was elevated with the underlying subcutaneous fat. The pedicle was gently retracted and the margins of the skin were sufficiently reflected both anteriorly and posteriorly to permit closure without tension. The pedicle was then converted into a tube by approximation of the skin edges with interrupted fine cotton sutures (Fig. 7). Between the second and third week after operation circulation in the tube was tested by application of a rubber tourniquet about the distal end of the tube. In all cases good circulation was maintained in the tube during a period of constriction with a rubber tourniquet. At the second operation the tube was divided at its lower end and the defect of the leg was closed by suture. The tube was then opened and sutured in place to the freshly mobilized skin edges about the area of the ulcer. The limbs were held in proper approximation so that the tube was not constricted and position was maintained with a plaster cast to both lower extremities (Fig. 7). In general the patients found this position comfortable. Three weeks later the cast was removed, the proximal end of the tube was divided and the free end of the graft was sutured in place.

In no instance was such a graft lost. In a single instance about 10 per cent of the distal end of the graft was lost but the small resulting ulcer readily healed and presented no difficulty. In one instance a small draining

Fig. 8. Photograph illustrating contractures of toes in trench foot, a, left. The patient had comfortable feet following amputation and revision of stumps, b.

sinus persisted in a portion of the suture line and considerably prolonged the patient's hospital stay. After efforts to obtain healing by saline compresses, curetting, and excision of the margins with a closure, a small sequestrum from the head of the metatarsal was finally discovered and healing occurred promptly after its removal.

When gangrene is limited to a portion of a toe and revision of the stump is necessary because of thin adherent skin or because of osteomyelitis, no harm results from the sacrificing of a small amount of tissue. When the metatarsal heads form the stump, however, it is my conviction that they should not be removed in order to permit bringing good skin over the stump. It is far better to cover such defects with full thickness transfer grafts. In Figure 6c is shown one patient in whom such a revision was carried out. Although the foot functions fairly well I have no doubt, in retrospect, that a much more comfortable and useful foot would have been obtained if a graft had been used and the metatarsal heads left undisturbed.

Stiffness and contractures of toes were not uncommonly seen in patients with trench foot without gangrene, and similar difficulties were sometimes encountered in patients who had sustained loss of tissue through gangrene. The stiffness of the toes could generally be satisfactorily cleared with physiotherapy and exercise. The commonest deformity resulted from an extensor contracture. Flexion contractures were fewer. Contracture was more common in cases of stumps of toes than where the entire toe was present. This condition was sometimes amenable to physiotherapy and the use of metatarsal bars. In a few instances in

which the contracture was severe and disabling, amputation was carried out. In such cases the deformity was generally so great that amputation was felt preferable to the conservative surgical methods (Fig. 8).

PROSTHESES

When all of the toes were removed a sponge rubber or cotton pad was placed in the distal end of the shoe to prevent the foot from sliding forward. In an occasional case where the great toe was present and the second or second and third toe had been amputated, a chamois covered sponge rubber pad which could be inserted between the toes and kept in place with a sock proved useful in preventing a hallux valgus deformity. In some patients with relaxation of the foot and discomfort on walking, resilient arch supports were helpful. In general the patients had little difficulty in standing or walking other than for slight or moderate discomfort in the metatarsal area. This pain on weight bearing was not peculiar to the patients who had undergone amputations, but occurred just as frequently in patients with trench foot who had had no gangrene at all. It was often helped by placing a second heel in front of the heel of the shoe or by the use of a metatarsal bar (1).

DISCUSSION AND CONCLUSIONS

Superficial gangrene in trench foot does not present a serious problem. Very often satisfactory healing takes place beneath the crust or following its separation. Occasionally superficial gangrene results in more serious difficulty because of the presence of underlying infection which may give rise to osteomyelitis. In such instances partial or complete amputation of toes may be necessary. Deep gangrene is a more serious difficulty. In the great majority of patients this gangrene is limited to portions of the toes. In a lesser number, entire toes are involved, and in some patients, gangrene is so extensive that the heads of metatarsals are left exposed following amputation.

Infection of a mixed character is present in the great majority of patients with deep gangrene. Such infection has been controlled satisfactorily with sulfadiazine or penicillin

and with the local application of warm saline compresses following removal of gangrenous parts. Spreading of infection into adjacent soft parts did not occur. Occasionally osteomyelitis was present in the stumps. The infection tended to retard healing somewhat and to interfere with the success of split thickness grafts. It is felt that streptomycin would be of help in regard to infection, as organisms resistant to sulfonamides and penicillin are commonly present.

Vasoconstriction, sometimes intense, was present in the majority of patients. It is felt that lumbar sympathetic ganglionectomy is a useful adjunct in the treatment of deep gangrene of trench foot and that it results in more speedy healing and in conservation of tissue. In case skin defects have resulted from the loss of parts, epithelization has often occurred rapidly and in many instances the resulting new skin has been sufficiently good to withstand the trauma of walking. When the defects are large, occasionally satisfactory outcome is obtained by permitting epithelization from the margins.

In general it is advisable to cover such areas with a split thickness or full thickness graft. If the ends of metatarsals are exposed, a full thickness covering of skin is generally necessary. This covering is best applied by means of a transfer graft from the opposite leg. The most suitable means of carrying out this skin graft has been found to be a tube transfer graft. Because of the atrophy present it was possible in the first stage operation to elevate the tube and to close the skin margins beneath it without tension. Should this step be impossible a double pedicle flap can be elevated and sutured back in position or converted into a tube after there is placed beneath it a split thickness graft. The stump is satisfactory for standing or walking if all the toes are removed or if parts of the metatarsal heads must be removed. If amputation must be carried out more proximally through the metatarsals, the stump is generally unsatisfactory.

A STUDY OF THE ABSORPTION CHARACTERISTICS OF SURGICAL CATGUT

GOTTFRED HAUGAARD, Cand. Polyt., LAWRENCE A. THOENNES, Ph.D., and
MARVIN J. HALL, Ph.D.

SINCE the introduction of catgut as a surgical suture material by Lister the problem of its absorption characteristics has been of vital interest to the medical profession. Numerous papers have been published and considerable time and energy have been expended in an effort to get a better understanding of the absorption process and of the best possible methods of controlling it so as to make available to the surgeons a product which is adequate to meet their needs. Some of this work has been carried out by investigators who have been handicapped by the need of obtaining their material through purchase on the open market and, consequently, have had no control over a number of factors which could have very definite bearings on their results. They have attempted to minimize this handicap by the multiplicity of their experiments and have succeeded in contributing much to the present knowledge concerning sutures.

We have been fortunate to be in a position in which we could obtain the raw material and process it ourselves so that all variables incident to the manufacturing process were controlled (chromicization, sterilization, et cetera). For this reason, and because we have occasion to introduce several new concepts, we believe that the results of our experiments will shed some new light upon the subject.

RELATIONSHIP OF TRYPTIC DIGESTION OF CHROMICIZED COLLAGEN TO SHRINKAGE TEMPERATURE AND THE CONTENT OF CHROMIUM

In vitro digestion of collagen. In order to correlate absorption of collagen implanted in the animal with proteolytic digestion, *in vitro* trypsin as well as pepsin have been used in the past. Kraissl and Meleney have used trypsin while Jenkins and Hrdina (5) used pepsin; however, no explanation has been presented for

the choice of either one of the enzymes employed.

There is no doubt that the peptic digestion is influenced to some extent by the same factors as *in vivo* absorption and that valuable information can be and has been obtained in the past by this method. Jenkins and Hrdina arrived at a nearly linear relationship between "the duration of tensile strength in tissue" and "digestion time in acid pepsin." Although the applicability of pepsin to these problems has been clearly demonstrated by Jenkins and Hrdina, we feel that an enzyme more closely resembling the proteolytic enzymes of the tissue (cathepsin, et cetera) would be a better choice. In this connection, it can be pointed out that the pH optimum for pepsin is between 1 and 2, while the optimum of the proteolytic enzymes of the tissue is around 7. Furthermore, pepsin digests undenatured as well as denatured collagen quite readily but undenatured collagen is very slowly absorbed in animals. It has also been observed that digestion with pepsin seems to carry the collagen through a gelatinous state before breaking it down to polypeptides, which is not the case in animal absorption.

In trypsin we have a proteolytic enzyme which meets our requirements better. It has its pH optimum in the same region as cathepsin, undenatured collagen is not (or at least is very slowly) hydrolyzed, and no gelatinous intermediate product is found. Due to difficulties of preparation we have avoided the use of cathepsin itself; however, we feel that trypsin for our purpose is an adequate substitute.

The trypsin preparation used was a crude preparation from Central Scientific Company (Chicago). No attempt at purification was made, as all the digestion results were relative in nature.

In some of our earlier digestion experiments we have used the technique of determining the

Fig. 1. Shrinkage temperature apparatus. B, base; C, battery clamp; H, heating element; P, pulley; S, screen; W, weight.

time it takes to break a strand immersed in the enzyme solution under mild tension. This technique, which was first introduced by Kraissl and Meleney, gives good, statistical results but is somewhat unreliable in a single experiment. This method was, therefore, replaced by determinations of the nitrogen content of the hydrolysates expressed as percentages of the initial collagen nitrogen present.

The shrinkage temperature. A collagen suture behaves in a remarkable manner when it is immersed in water and the temperature of the water gradually raised. At a rather definite temperature it contracts in the direction of the fiber axis and becomes elastic like rubber. This transformation temperature, or shrinkage temperature, can be measured nearly as accurately as a melting point of an organic compound. That a change in the configuration of the molecule has taken place can be clearly observed by x-ray diffraction and also deduced from the fact that collagen, which prior to the heating was practically indigestible by trypsin, now becomes readily digestible.

The shrinkage of collagen is without doubt closely related to the denaturation of a soluble

Fig. 2. Typical measurement of shrinkage temperature of surgical gut.

protein and can, therefore, be characterized as a denaturation since the mechanism of both processes is fundamentally the same. Thus, the change in viscosity of a protein solution when denatured is explained as a change in shape of the protein molecule.

The measurement of the shrinkage temperature is conveniently done in the following way (Fig. 1). The catgut attached to a base B is suspended in a vertical position in a metal container and submerged in water. The upper part of the gut is attached by means of a battery clamp C to a cord which runs over a nearly frictionless pulley P, having a weight W attached to the free end. The weight is 1 gram heavier than the battery clamp and serves to keep the catgut straight when in a swollen condition. The position of the weight is read against a screen S which is covered with a piece of graph paper. The bath is slowly heated and a reading is taken for every degree rise in temperature. Figure 2 shows a typical measurement. The intersection point between the two lines gives the shrinkage temperature which, in this example, would be 51.8 degrees C.

The process of chromicizing catgut sutures is essentially a tanning procedure. In the tanning industry measurements of shrinkage temperatures are more and more replacing the old boiling test as a control of the degree of tanning. Apparatus similar to the one presented here are available commercially for this purpose. For physicians it is interesting that this shrinkage was used as early as 1873 by Engelmann as a physiological demonstration of the phenomenon of muscle movement.

The shrinkage temperature is, as could be expected, a function of pH of the solution; thus, undenatured catgut has a shrinkage temperature of about 60 degrees C. in neutral solutions and around 45 degrees C. in solutions of pH 3.0. The salt concentration also has an influence and, characteristically, the calcium ion lowers the shrinkage temperature considerably more than any other ion. The condition of the catgut itself (for instance, content of chromium or degree of denaturation) profoundly influences the shrinkage temperature. In our studies, we have not been interested in a study of the influence of pH or different salts on the shrinkage temperature but rather in the use of the shrinkage temperature as a means of characterization of the catgut itself. In all the measurements presented we have, therefore, kept the pH constant at 6.8 by using Sørensen's phosphate buffer solutions. For further information on this subject, which without doubt is of far-reaching physiological interest, the reader should consult the recently published book of McLaughlin and Theis, in which the chemical significance of the shrinkage phenomenon is discussed in detail.

Most of our digestion experiments have been made in connection with animal experiments and will be described in the following section; however, two experiments, which demonstrate the importance of the shrinkage temperature as a characterization of the catgut suture, will be reported here.

The tryptic digestibility of collagen is, as shown convincingly by W. Grassman, highly influenced by a prior heat treatment. As previously stated, collagen which has not been denatured is practically indigestible by trypsin; however, strands partly or completely heat denatured are digestible and, the more intense the preceding heat treatment, the higher the digestibility.

Heat treatment of collagen in the presence of moisture produces a higher degree of denaturation than a similar treatment under anhydrous conditions. Consequently, catgut manufacturers carry out their sterilization process in the absence of moisture.

Chromicized catgut sutures of three different chromium contents were divided into two

groups. The two groups were given different heat treatment (under conditions resembling the sterilization process) resulting in strands of different degrees of denaturation and, hence, different shrinkage temperatures. In another experiment, strands of different chromium contents were given the same heat treatment. In both experiments the shrinkage temperature and the relative tryptic digestibility were determined. The enzyme solution used was a 0.5 per cent solution of trypsin in phosphate buffer at pH 6.8; 10 cubic centimeters of the solution was used to 0.4 gram of collagen. The temperature was 36 degrees C. and the digestion time, 48 hours. The results of both experiments are compiled in Table I, and the figures are arranged according to decreasing shrinkage temperatures.

When the figures are arranged in this manner, it is seen that the tryptic digestibility increases when the shrinkage temperature decreases in both experiments. When the heat treatment has been varied (the first experiment), the chromium content does not follow the shrinkage temperature and digestibility. However, in the second experiment where all of the strands have been heat treated in the same way the chromium content follows both the shrinkage temperature and the digestibility in an orderly fashion.

It can thus be stated that surgical catgut is characterized not only by the chemical treatment it has undergone (chromicization or use of other tanning agents) but also by the degree of denaturation caused by the sterilization process and recorded by the shrinkage temperature.

As will be demonstrated later, we have found a parallel relationship in our animal experiments.

THE PROPERTIES OF COLLAGEN SUTURES AFTER PERIODS OF IMPLANTATION IN ANIMALS

Jenkins and Hrdina (4) have found a satisfactory correlation between the absorption characteristics of surgical catgut in animals and in the human. While they worked mainly with dogs, it has been our experience that rabbits may be used to equal or better advantage in this type of work. Consequently, we have used rabbits in most of our *in vivo* experimental investigations.

Sutures were imbedded in the dorsal muscles of the rabbits while they were under nembutal anesthesia. All implantations were carried out under aseptic conditions. The sutures were passed through the skin and into the muscles of the pelvic region by means of mattress needles about $7\frac{1}{2}$ inches long drawn through the muscles of the back parallel to the dorsal surface of the animal and brought out through the skin in the scapular region. They were tied at each end to wound clips attached to the skin, care being taken to allow a slight amount of slack at each end so as to prevent too much tension being applied to the suture as the animal changed position. The area was then covered with a sterile gauze pad which was held in place by sterile bandages. Finally, the bandages were covered with adhesive tape. This technique is similar to that previously described by Howes.

The sutures were removed after predetermined intervals by loosening the wound clips and freeing the sutures after which they could be pulled out of the muscle without difficulty. The tensile strength was measured on a Scott tensile strength machine. While some investigators have dried the sutures before measuring the tensile strength, we felt that they should be tested in as nearly as possible the same condition as obtain in the tissue. For this reason all sutures were placed between damp towels and the tensile strength measured before any loss of fluid had occurred. Controls were kept between damp towels for $1\frac{1}{2}$ hours before testing since it was found

TABLE II.—DIAMETER OF VARIOUS SIZES OF CATGUT USED

that such treatment gave results similar to those obtained from sutures which had been in the tissues about 45 minutes. This level was chosen as the control because it was found that catgut sutures decrease in tensile strength as they imbibe fluids from the tissues. The tensile strength level becomes fairly constant after 45 minutes in the tissues, and imbibition of fluids alone does not further reduce the strength. Approximately two thousand sutures were tested in this manner. This method of testing enabled us to determine the functional life of the sutures which we believe to be as important from the surgeon's point of view as the complete absorption time.

EFFECT OF IMPLANTATION IN ANIMALS ON THE TENSILE STRENGTH OF CATGUT SUTURES

In the first phase of this study type Q sutures with a chrome content of 0.6 per cent (Table II) were used. These were implanted in the dorsal muscles of rabbits in the manner described, 6 sutures being placed in each animal. The sutures were removed and the tensile strength measured after periods of 3, 5, 7, 9, 11, and 15 days. Two tensile strength measurements were made on each suture, and the average of 12 measurements made on 6 sutures from the same animal was taken as the final value. The average tensile strength was then plotted against the number of days in the rabbit. The sutures used for any particular series of experiments were all chromicized, tubed, and sterilized at the same time so as to eliminate variations in these pro-

¹All sutures were chromicized by a method which gave uniform chromicization throughout the suture.

Days in animal	Chromic oxide per cent	Shrinkage temperature Centigrade	Wet tensile strength (in pounds)	Relative tryptic digestibility (per cent into solution)
Control	1.48	63.2	15.5	6.6
3	1.20	57.8	10.3	30.1
7	1.18	56.3	8.0	44.2
11	1.06	54.8	3.5	77.5
15	0.00	54.2	4.0	71.4

cedures which might affect the rate of absorption. The chrome content of each batch of sutures was determined as well as the shrinkage temperature as a further check on their uniformity.

It was found that the tensile strength decreased in a fairly linear fashion for about 7 days at which time they retained approximately 30 per cent of their original wet tensile strength. From the seventh to the thirteenth day there seemed to be little further decrease in tensile strength (about 10%). From the thirteenth to the fifteenth day there was a rapid decrease so that after 15 days the sutures had little or no tensile strength remaining (Fig. 3).

Plain catgut studied in a similar manner decreased much more rapidly in tensile strength. After 3 days, only 33 per cent of the original tensile strength remained, and all but about 10 per cent of the strength had been lost after 5 days (Fig. 3).

These experiments were then repeated with surgical gut of various sizes (Type L to Type S) and chrome contents. The residual tensile strength curve had the same general shape in all cases and, what seemed more significant, the rate at which the tensile strength decreased was approximately the same regardless of the size of the suture. The exception to this seemed to be the very large sizes, particularly Type S, in which the initial rate of decrease in strength was slightly higher. This was attributed to the increased foreign body reaction produced by these sutures.

By chrome tanning alone it is difficult to make sutures which have a functional life greater than 15 days. In the case of Type Q sutures, it was possible, by increasing the

Fig. 3. The effect of implantation in animal tissue upon the wet tensile strength of surgical gut.

chrome content to 1.25 per cent, to extend the life of the suture approximately 6 days (Fig. 3). This holds also for smaller sizes on a percentage basis, but the actual strength of the extreme small sizes is so low that there is no improvement of practical significance. In the case of larger sizes an increased chrome content does not improve the suture appreciably due to the increased foreign body reaction.

To extend the absorption time of a suture appreciably beyond 15 to 18 days other procedures in addition to chromicization must be employed. This was found to be true regardless of the method of chromicization.

It has been assumed by some investigators that the decline in tensile strength of catgut in the tissues is a relatively constant factor. While the results of dry tensile strength measurements may lead to this conclusion, it is evident from the experiments just described that the wet tensile strength measurements of chromicized sutures indicate that the tensile strength drops in a fairly linear fashion for a period and then maintains quite a constant level for a time after which there is a rapid loss until all strength is gone.

As we have found no loss in weight of the strands imbedded in the animal up to periods of 10 days, this characteristic shape of the curve cannot be explained as a consequence of loss of collagen material due to enzymatic activity, but other factors must be involved. In order to follow this problem more closely we have made a number of experiments where

TABLE IV.—EFFECT OF HEAT DENATURATION ON IN VIVO ABSORPTION OF PLAIN CATGUT

Heat treatment	Initial shrinkage temperature degrees	Initial tensile strength (Pounds)	Tensile strength after 7 days (Pounds)	Per cent residual wet tensile strength	Initial digestibility (per cent into sol)	Digestibility after 7 days (per cent into sol)
No treatment	61.5	7.7	6.3	82.3	7	27.3
Dried 16 hrs. at 100°C.	55.8	5.9	2.9	49.3	10.8	35.1
Complete sterilization process	47.1	7.0	1.2	17.0	70.1	97.8

we have examined the strands taken out of the animals in the following manner: the shrinkage temperature was measured, the strands were analyzed for chromium, and the relative tryptic digestibility was determined. The results of a typical experiment are presented in Table III.

It was found that there was a decrease in the chromium content and in the shrinkage temperature and an increase in the tryptic digestibility of the suture which paralleled the decrease in wet tensile strength after varying periods in the animal.

The dechromicization of the sutures is probably due to the transfer of the chromium from the collagen to other protein compounds in the surrounding tissue. This is in line with the observation of McLaughlin and Adams (8) who reported that, when chrome leather was immersed in water with unchromicized pieces of hide, there was a dechromicization of the tanned leather and a corresponding chromicization of the untanned pieces. Jenkins (6) and his co-workers have reported that a similar phenomenon takes place in living tissues when chromicized sutures have been imbedded therein. They observed that the phagocytic cells around the sutures took on the color characteristic of chromic catgut to such an extent that for some time after the catgut had been absorbed these chrome stained macrophages simulated the gross appearance of unabsorbed chromic catgut.

The relationship between chromium content, shrinkage temperature and tryptic digestibility has been discussed for *in vitro* experiments in the first part of this paper (Table I). The dechromicization which takes place in the tissue of animals has been shown to bring about a corresponding decrease in the shrinkage temperature and an increase in the digestibility of the suture; however, the increase in digestibility in the tissues is greater

than can be accounted for by the loss of chromium. We have shown in the first part of this paper that the degree of denaturation caused by the sterilization process has an effect upon the *in vitro* digestion of collagen sutures. Similar results were obtained by *in vivo* experiments (Table IV). A series of experiments was conducted in which the tensile strength and the tryptic digestibility of plain catgut sutures which had been heat treated to produce different initial shrinkage temperatures were measured after 7 days in animal tissue. The residual tensile strength and the relative digestibility were found to vary inversely with the initial shrinkage temperature. These experiments with plain catgut indicate that, while the products of metabolic activity in the tissue have a denaturing effect of their own upon the collagen which has an influence upon the residual tensile strength and the tryptic digestibility, the denaturation of the suture by the tissue fluids is influenced to a considerable extent by the heat treatment of the suture during the sterilization process. *We can here again emphasize the fact that the initial shrinkage temperature is as important as the degree of chromicization for adequate suture absorption.*

The increase in tryptic digestibility after chromicized sutures have been implanted in tissue is remarkable. While only about 7 per cent of the control strand went into solution under the experimental conditions, approximately 70 per cent was dissolved under the same conditions after 11 to 15 days in the animal (Table III). *For all practical purposes chromicized sutures can thus be considered non-absorbable at the time that they are imbedded in the animal, but through a process of dechromicization and denaturation they become absorbable.* As a result of these processes they lose tensile strength and gradually become more susceptible to the action of the tissue enzymes.

This mechanism seems to be ideal for a surgical absorbable suture, and any new absorbable suture material which may be introduced in the future probably should have properties which essentially conform to this mechanism.

SUMMARY

A study of the mechanism of absorption of surgical catgut and of some of its absorption characteristics has been presented. The relation of the tensile strength, shrinkage temperature, dechromicization, and tryptic digestibility of sutures before and after implantation in animals were studied. The experimental material presented leads to the following conclusions:

1. The absorption characteristics of the suture are determined not only by the degree of chromicization but also by the initial shrinkage temperature.

2. The wet tensile strength of a chromicized suture decreases in a fairly linear fashion for a time after which there is a period during

which there is little further loss of strength followed by a rapid decline until little or no strength remains.

3. A decrease in shrinkage temperature parallels the loss of tensile strength.

4. The chromium content of a suture decreases during the period in which it is in the tissue.

5. There is an increase in tryptic digestibility proportional to the time of implantation.

THE EFFECT OF THE ANTICOAGULANTS ON POSTPARTUM BLEEDING

ALLAN C. BARNES, M.S., M.D., and H. K. ERVIN, M.D., Columbus, Ohio

THE clinical use of the anticoagulants, both heparin and dicoumarol, has extended continuously since their original introduction. They are not only accepted agents in the therapy of intravascular clots, but their routine administration to surgical patients for prophylaxis has also been suggested and investigated (1, 2). The use of these drugs in puerperal thrombophlebitis has been limited, however, due apparently to a reluctance to administer them to patients experiencing vaginal bleeding, and the fear of postpartum hemorrhage. Pfeiffer and Sain specify that the bleeding of the puerperium represents a definite contraindication to the use of the anticoagulants, although they cite no studies to justify this statement. Davis and Porter have more recently reported the use of dicoumarol for thrombophlebitis occurring in the puerperium, but their data includes no estimation of the influence of the drug on the vaginal bleeding other than a statement that they observed no instances of gross hemorrhage in their patients, and we have been unable to find studies which record measurements of postpartum blood loss during heparin and/or dicoumarol therapy.

In the face of the known incidence of postpartum thrombophlebitis and phlebotrombosis (7), it was felt desirable to have more accurate information on this subject, and the present paper reports measurements of vaginal blood loss in patients receiving dicoumarol and heparin during the early puerperium.

Materials and methods. Blood loss studies beginning 1 hour postpartum and continuing throughout the period of hospitalization were made on 30 consecutive primiparous patients. All the patients had reached term and had uncomplicated labors with spontaneous delivery

or outlet forceps; episiotomy was performed on each. With the exception of the drugs under study, all of these patients were on a similar therapeutic program. Vitamin K was given to none of them; the same anesthetic agent (cyclopropane) was used in all deliveries; the oxytocic schedule included ergotrate (1/320 grain) intravenously following the delivery of the placenta, and the same dose administered by mouth 3 times a day for the first 3 postpartum days.

All perineal pads from each patient were collected over the period of time the patient was in the hospital. The pads of the preceding 24 hours were washed out daily in a measured amount of water, and a hemoglobin determination was made on the wash water. While this method was checked for accuracy with known amounts of venous blood distributed over several pads and dried an equivalent length of time, no attempt has been made in this report to reduce to grams of hemoglobin the readings obtained. The figures serve for accurate comparison between the group of controls and the treated patients, and the relative blood loss rather than the absolute blood loss has been our interest.

In addition to the blood loss data, prothrombin levels expressed as percentage of normal (Quick) were obtained on the control group and dicoumarol treated patients as well as the clotting times (Lee and White) on the heparinized patients and on controls.

Controls. The 11 patients who served as controls uniformly showed the marked elevation of prothrombin level which has been noted in the normal postpartum patient (6). Readings as high as 130 per cent were obtained (second day following delivery), and with the exception of one reading of 85 per cent on the third postpartum day, no patient fell below 100 per cent until after the fifth day. The average daily prothrombin levels among these patients, starting with the first post-

From the Department of Obstetrics and Gynecology, The Ohio State University Medical School.

partum day, were: 108, 111, 112.5, 113.25, 100.1, 109.2, 109, 101, 98 per cent. There were not enough patients in this group who remained after the ninth postpartum day to make the average figure of value. These prothrombin percentages are plotted graphically in Figure 1 as the dotted line (A). The solid line (B) represents the average blood loss of this control group during the same period of time.

Dicoumarol. Fourteen patients were given dicoumarol in doses adequate to depress their prothrombin levels to the therapeutic range. Three hundred milligrams were given during labor, 200 milligrams each of the first 2 days, and subsequent dosage was adjusted by the prothrombin determinations. In general, it was felt desirable to have the prothrombin percentage rising toward normal at the time of discharge, and the drug was discontinued 24 to 48 hours before the patient was to leave the hospital. The average daily prothrombin times for these patients, starting with the first postpartum day were: 90.7, 54, 33, 37.3, 20.6, 43.5, 37.7, 54.6, and 63 per cent. At least 12 of the patients are represented in each daily average except the first (6 patients), the 6th (10 patients), and 9th (7 patients). On these days technical difficulties or discharge from the hospital interfered with obtaining prothrombin readings on a larger group. The broken line (C) in Figure 1 records these levels.

The blood loss for this group is shown in the broken line (D) on the same chart. It will be seen that there is no significant difference between the average blood loss of this, the treated group of patients, and the controls (line B). The variation in the two curves on the first 2 days is not great and is not related to the period of prothrombin depression. The 5 day period that the prothrombin level was maintained below 50 per cent (i.e. more than 16.25 seconds undiluted) was perhaps brief compared to the period sometimes required for therapy, but the blood loss at the end of this time had dropped toward the nonmeasurable point, and we could see no advantage in prolonging the period of treatment. In one patient whose medications were continued through an oversight, the prothrombin level was maintained below 10 per cent (over 37

Fig. 1. The scale to the left represents the prothrombin percentage from 20 to 120. Curves A and C give the prothrombin readings for control and dicoumarol patients respectively. Curves B and D record blood loss figures for control and treated patients respectively plotted against the arbitrary scale (0 to 100) on the right.

seconds undiluted) her 7th, 8th, and 9th days postpartum. During this time the patient was ambulatory, but her blood loss was small and did not differ from that of the control group.

It can be noted from the results as recorded in lines B and D that if any given postpartum day is selected, the blood loss of the treated patients is not significantly more than, or is less than, that of the controls. The total blood loss, arrived at by adding the arbitrary figures for each day together, differs but slightly between the two groups, with the treated group having more. No correlation between blood loss and prothrombin rate could be noted in the dicoumarol treated patients; the greatest blood loss was on the second day, the lowest prothrombin percentage was on the fifth day.

Additional observations. Initially in the experiment when marked differences in blood loss were considered possible, hematocrit readings were taken every other day on all patients. It was felt that these would provide a more accurate index than would hemoglobin determinations of the effect on the patient of any excessive blood loss. There were no episodes of excessive blood loss, and the hematocrit remained comparable between controls and treated patients. There was no alteration in the degree of uterine involution at

the time of the patient's discharge from the hospital, nor were any toxic side effects noted.

Bleeding and clotting times obtained on the nursing babies showed prolongation in over one-third of the cases. These reactions were not consistent: in 2 cases both were prolonged, in the other 3 only the clotting time (capillary tube method) was increased. It is not felt that these studies performed on toe or heel blood are sufficiently delicate that the results would bear close scrutiny. In view of the report by Field, however, that rat litters nursed by dicoumarolized females showed hemorrhagic tendencies (7), it might be wise to consider weaning a baby whose mother required prolonged medication with dicoumarol.

Heparin. The action of heparin is more rapid, and there has been an increasing tendency in the presence of the indications for anticoagulant therapy to administer heparin the first 24 or 48 hours while the slower acting dicoumarol is having its effect (6). Accordingly, the patients in this study receiving heparin were maintained with prolonged clotting times for only a 24 hour period on either the first or the second day postpartum. Four cubic centimeters of heparin were administered intravenously, and beginning 4 hours later, the same dosage was administered by the intramuscular route every 4 hours. Clotting times were taken every 2 to 3 hours. Only 5 patients were followed in this manner, but the results in all were consistent, no patient varying more than 6 per cent from the average of the group, and it was felt that a definite index was obtained of the amount of blood lost by the heparinized patient.

Results. The clotting times of the controls checked during the first 48 hours postpartum were all normal (average $7\frac{1}{2}$ minutes), and a significant puerperal alteration similar to that observed in the prothrombin time was not found. During the 24 hour period of treat-

ment in the heparinized group, this clotting time was maintained between 20 and 25 minutes with the exception of 1 patient who, on the dosage outlined, remained between 15 and 18 minutes. During the entire first postpartum week, the blood loss on these patients was the same as that of the controls. There was neither an immediate nor a delayed effect from the heparin administration. Two of the episiotomy wounds, however, developed hematomas, and one of these suffered a partial breakdown. Aside from this complication, the treated patients and the control group presented the same findings.

SUMMARY AND CONCLUSIONS

No patients with postpartum thrombophlebitis were treated, and the present note is not concerned with the therapeutic status of heparin and dicoumarol in this condition. The study was undertaken only to determine whether or not, should these drugs be indicated, the vaginal bleeding prohibited their use. Although the present series is not large, the patients have been followed carefully, and we are unable to find evidence that the anticoagulants significantly increased puerperal blood loss. The customary precautions in connection with the use of these drugs should be scrupulously observed (1), and the weaning of the baby is to be considered, but the data obtained would indicate that heparin and dicoumarol are not necessarily contraindicated in the postpartum patient.

TALC GRANULOMA

A. L. LICHTMAN, M.D., JOHN R. McDONALD, M.D., CLAUDE F. DIXON, M.D., F.A.C.S.,
and FRANK C. MANN, M.D., Rochester, Minnesota

DESPITE many reports on the dangers resulting from the use of talc many surgeons remain skeptical and continue to use it as a powder for gloves. A study of the occurrence of granulomatous lesions produced by talc and their mode of production, therefore, seemed warranted.

The material reported in this paper is part of the data derived from a study of birefringence in tissues and an investigation of changes in tissues in human beings and in laboratory animals produced by doubly refractile foreign bodies, made visible by use of polarized light microscopy. In the main only the data on talc and the study of the reaction of tissue to talc will be recorded here, although other phases of the entire study will be referred to from time to time when they are pertinent.

THE PROPERTIES, USES, AND DANGERS OF TALC

Talc is a hydrous magnesium silicate with a melting point of 1,380 to 1,530 degrees C. Commercially dispersed talc consists of mixtures of talc, serpentine, dolomite, or tremolite. Reports on the solubility of talc vary from 0.2 to 100 milligrams per 100 cubic centimeters because each investigator has a different interpretation of what constitutes a particle in solution. Talc moieties are complex and exert a definite effect on the environment without being in actual solution themselves.

The material leached out of a talc crystal during suspension is not the same as the parent substance. The degree of hydration of this derivative substance determines its toxicity. For example, a mole of alpha silicic acid may bind as many as 330 moles of water. The size, shape, and cleavage of a talc particle and its surface energy affect its so-called solubility. In the body, alteration of the pH and the presence of protein in tissue fluids alter the size and characteristics of the dispersed aggregates.

From the Division of Surgery and Section on Surgical Pathology, Mayo Clinic, and Division of Experimental Medicine, Mayo Foundation.

Abridgment of part of a thesis submitted by Dr. Lichtman to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Ph.D. in Surgery.

To demonstrate these facts, talc and asbestos particles were placed in water, saline, body fluids and macerated tissues for 6 months. When these specimens were examined under polarized light, myriads of particles in brownian movement were seen in suspension. Particles of this dispersed size (0.5-10 microns) are the ones that do the greatest damage.

Talc is used extensively and may find its way into the body in many ways (Table I). The dangers of talc were first recognized by those interested in inhalation of this substance by miners and processors of talc (31). Extensive studies were made on the incidence and importance of talc pneumoconiosis (2, 7, 8, 12, 15, 19, 20, 27). The general impression was that talc produces a fine nonprogressive fibrosis.

Talc has been administered to animals by dusting (11, 12, 19) and injection into veins (12) and lymphatics (28). Its introduction into the testes of the guinea pig caused marked proliferative reaction. Tremendous variation was noted in the response of different tissues and of the same tissues in different individuals and species.

Pleural poudrage of talc was suggested for the production of selective pleural adhesions preliminary to operations on the lungs (4) but it was noted that it might increase susceptibility to tuberculosis (5). Talc has been rubbed on the pericardium in an effort to produce parasitic myocardial circulation (3, 24, 29, 30).

In 1933 Antopol reported 6 cases in which talc and lycopodium powder formed granulomas after operations. Since then granulomas and adhesions producing intestinal obstruction have been frequently attributed to talc introduced by surgeons' gloves (6, 9, 10, 13, 14, 17, 18, 21-23, 25, 26). It has been reported that 22.6 per cent of surgeons' gloves are perforated during operations permitting seeding of talc from the finger tips (32).

CLINICAL DATA ON LESIONS PRODUCED BY BIREFRINGENT PARTICLES FROM VARIOUS SITES

Many talc granulomas were discovered by examination under polarized light of tissues obtained in cases in which there were adhesions, unusual scars, nodules, sinuses or granulomas, in which tuberculosis was in an unusual site or in which multiple operations had been performed.

TABLE I.—ROUTES, OCCUPATIONS, AND USES OF TALC WHICH MAY PERMIT ITS INTRODUCTION INTO THE HUMAN BODY

- I. Through air passages: inhalation for long periods of high concentrations of talc
 - A. Mining, processing, and packing of talc
 - B. Dusting rubber for prevention of deterioration and sticking
 1. In factories
 2. In operating rooms
 - C. Scouring and polishing with talc powders
- II. By mouth
 - A. Bleaching agent for barley
 - B. Cleansing agent for beans, coffee, corn, peas, peanuts, and barley
 - C. Dusting agent (with starch) and coating for molds and tables in manufacture of candy and chewing gum to prevent sticking
 - D. Packing and conserving agent for fruits and vegetables
 - E. Binder in pills and lubricant for tablet dyes
 - F. Filtering medium in refining and purifying sugar
 - G. Ingredient of tooth powders and tooth pastes
 - H. Ingredient in glazes, coating and filler for paper used for wrappings for foodstuffs
- III. By other routes
 - A. Coating of talc on vaginal and rectal suppositories
 - B. In antiseptic dusting powders used on wounds
 - C. In cosmetics and dusting powders for the skin
 - D. As a preservative and lubricant for rubber gloves used in operations

The mere presence of talc in a microscopic section was not considered significant because talc is frequently suspended in the air in operating rooms and because the specimen may be handled with rubber gloves in the laboratory and thus talc may be added during the preparation of the section. Gauze used to wrap specimens may add cotton fibers too. In fact, it was difficult to find a section without talc on it when the laboratory was adjacent to the operating rooms. Because of these facts, only those crystals which were associated with a definite surrounding inflammatory response were considered as significant. The nature of this work necessitated the elimination from consideration of any questionable particles and it was considered wiser to err on the side of rejection of any particle around which the foreign body response was not clear cut.

Peritoneum. In 100 consecutive surgical cases in which dense adhesions resulting from multiple previous operations on the abdomen were found, specimens of the adhesions were sectioned on the freezing microtome and studied by means of polarized light under the microscope. In 21 (21 per cent) of these cases talc crystals were found with a surrounding foreign body response. In 6 (6 per cent) a large amount of talc was present and the reaction was extensive. While the degree of reaction in these 6 cases was so great, and there was

no doubt of the part played by the talc in the production of the adhesions, the concentration of the talc and distribution of the reaction in the other 15 cases did not permit a definite conviction as to the rôle of the talc. Cotton lint fibers also were found in foreign body giant cells in these cases.

Nodular lesions of the peritoneum were examined next. In 4 cases definite talc granulomas were found. In these 4 cases small yellowish white nodules studded the peritoneum, mesentery, and omentum. In 1 of these cases lymphoid granules had contributed to the granulomas.

The tubercle-like appearance of the granulomas in these cases prompted us to re-examine tissue removed in cases in which a diagnosis of non-caseous tuberculosis of the peritoneum had been made. In 6 of the 102 cases of this condition in which lesions considered to be those of non-caseous tuberculosis were examined, the tubercle-like lesion had been produced by talc. In 5 other cases in which talc was not present, some of the tubercles apparently were actually foreign body responses to cholesterol esters contained in the nodule. Thus by the use of polarized light microscopy, the talc and cholesterol ester crystals, which were obscure on routine examination, became apparent. During examination of peritoneal lesions 6 cases were found in which birefringent vegetable fibers, originating from a previous perforation of a peptic ulcer, had formed granulomas. These were made obvious by the use of polarized light.

When concomitant trauma, abrasion, and infection had occurred, the talc if present in high enough concentration had produced dense adhesions with proliferation of a moderate amount of fibrous tissue. The granulation tissue in the adhesions was well vascularized. There was not enough fibrous tissue to cause obliteration of the vessels such as occurs in granuloma caused by silica. When simple inoculation of the talc had occurred with little infection or trauma, the talc tended to form plaques and nodular lesions were produced rather than dense adhesions.

These findings suggest that great caution should be observed about accidentally introducing talc into the peritoneal cavity in cases of tuberculous peritonitis. It would seem that talc may accelerate the progress of a tuberculous infection of the peritoneum.

Scars, sinus tracts, and lesions of skin. Nodules developing in scars left by operations are a source of concern to the surgeon and the patient. The patient is anxious about the cosmetic effect particularly if the scar is about the face and neck

from the prolonged use of suppositories dusted with talc, dusting powders, and other medications containing talc. Although the intact mucus membrane will not adsorb talc, the conditions prompting the prolonged use of rectal and vaginal medication are usually associated with erosions, ulcerations, and fissures. These granulating surfaces may adsorb talc particles and include them in a foreign body reaction.

In 25 consecutive cases in which biopsy revealed chronic cervicitis, the tissue removed was examined under the polarized light microscope and talc was found to have caused some reaction in 2 of them. In neither of these cases was the degree of reaction sufficient to account for the entire inflammatory response but it certainly may have been a factor in causing the persistence of the lesion. In these 2 cases, the lesion was suspected of being malignant on gross examination.

Two hundred specimens of inflammatory rectal mucosa were examined after removal in the course of hemorrhoidectomies. Although talc was found in many of these tissues, none of them showed a marked foreign body response and only 12 showed a minor foreign body response to the adsorbed talc.

In addition 2 definite talc granulomas were found in which rectal stricture was so marked that radical resection was performed.

Granulomas produced by foreign bodies such as oil or talc, introduced into the rectal tissues by injection for the treatment of hemorrhoids, by a gloved finger covered with talc or petroleum jelly, or suppositories aided by trauma, have on occasion been considered as malignant by most experienced diagnosticians. Biopsy may reveal a nonspecific inflammatory picture or the presence of pseudotubercles may suggest tuberculosis. Time can be saved by the examination of fresh-frozen sections under polarized light. On this examination the talc crystals as a center of the foreign body reaction are immediately apparent or the oleoma is self-evident. If the pathologist does not give such a definitive diagnosis, the patient will be subjected to repeated biopsies to rule out a malignant lesion. The granuloma may cause marked obstruction and radical therapy may be necessary.

The gall bladder. The finding of the following talc granuloma in the gall bladder was accidental and not by intentional investigation. It was encountered in a study of the cholesterol esters in the gall bladder.

Eleven years previously the patient had undergone cholecystectomy for cholecystitis with cholelithiasis. Little relief resulted and postoperatively the patient complained

of pain in the epigastrium and a tender mass in the right lower quadrant of the abdomen. Because of the persistence of these symptoms for 11 years, cholecystectomy was performed at which time dense adhesions to the stomach and colon were encountered. The wall of the gall bladder was markedly thickened and the pathologist suggested that a sarcoma of the gall bladder might be present. The adjacent lymph node was considered tuberculous. On re-examination with the aid of polarized light it was found that the gall bladder and lymph node were loaded with talc and cholesterol ester crystals. The close-packed pseudotubercles closely resembled a sarcoma lesion (Fig. 3).

The type of cholecystostomy tube used 11 years before was not known but it probably carried the talc in to the gall bladder and in all probability some petrolatum jelly too.

Gastroenteric stomas. Sixty specimens from the walls of excised malfunctioning gastroenteric stomas were subjected to examination by means of the polarizing microscope. In 8 (13.3 per cent) of them a large amount of talc was found in the wall around the stoma and a marked foreign body reaction was associated (Fig. 4). In 8 others a limited amount of talc was found. Foreign body reactions to the suture material used in the creation of the anastomosis also were present.

The talc in these cases may have been derived from the rubber-shod clamps used in making the anastomosis. The part the talc plays in malfunction of a gastroenteric stoma of adequate physical size is a matter of conjecture and a positive opinion would be perilous. Some evidence of the profound effects on the intestinal wall of intraluminal talc granulation tissue can be derived from the experimental work on the production of fecal fistulas which will be reported later in this paper.

It was deemed wise to compare this series in which the gastroenteric anastomosis was taken down because of poor function with a group of cases in which it was excised because of an anastomotic ulcer. In this latter group the function of the stoma was usually good. Tissue from the site of 100 such stomas was examined; the tissue from 4 (4 per cent) contained a marked amount of talc and from 3 a slight amount. The greater incidence of talc at the site of the malfunctioning stomas suggests the possibility that the granulomatous tissue in the wall of the stoma contributed to the poor function.

NONCASEOUS TUBERCULOSIS OF ILEUM AND REGIONAL ENTERITIS

From the findings presented thus far it can be seen that on occasion talc granuloma may simulate tuberculosis and that it may be diagnosed as tuberculosis. While large talc crystals can be seen in ordinary light when the field is darkened, particles between 0.5 and 10 microns in diameter

which cause most of the damage can be seen clearly only with the aid of polarized light. In view of the number of substances and products of inflammation which may produce pseudotubercles in some species (Table II), the unsupported morphologic diagnosis of hyperplastic noncaseous tuberculosis in cases in which tubercle bacilli are not demonstrable by staining, culture or guinea pig inoculation is subject to question. Many pathologists now call such lesions sarcoids.

So-called regional enteritis often consists of hyperplastic tissue in which there are pseudotubercles. It occurred to us that before 1932 many lesions now called "lesions of regional enteritis" would have been classified as hyperplastic noncaseous tuberculosis. In spite of the controversial nature of the problem it was decided to re-examine under polarized light the specimens of hyperplastic tuberculosis of the ileocecal region seen at the Mayo Clinic. By examination of multiple sections of the specimens and review of the history in 193 of these cases, the impression that a large number of these would be considered cases of regional enteritis in the present day was verified. One aspect of this problem is of interest in this study. In 49 of the 193 cases of so-called hyperplastic tuberculosis birefringent crystalline material was found. Extensive study of specially stained sections failed to reveal tubercle bacilli in any of the tissue available for study in these 193 cases. In 33 of the 49 cases, the amount of the crystals was large and the reaction appeared to be result of the presence of the crystals (Fig. 5). In 16 of the cases the amount of the crystals was small, and no definite conclusions could be drawn about their relation to the reaction. The magnitude of birefringence of the crystals in all 49 cases was high and negative in sign. As far as the petrographic analysis could go, the crystals resembled talc crystals. They were subjected to incineration study (Fig. 6) and the silicate nature was verified by comparison with adjacent serial sections. The crystals were not calcium deposited by a tuberculous infection for the birefringence of these apatite crystals is of low magnitude and the sign is positive. Furthermore, calcium salts, when stained with polychrome methylene blue take on a blue color, and do not provoke a foreign body reaction. Efforts to identify these crystals were fruitless.

Experimental investigation was limited to the roundabout method of trying to reproduce the lesion. Since only half of the patients had had previous operations involving the right lower quadrant of the abdomen, it could not be assumed that the crystals had been accidentally placed in the abdomen by the surgeon at the first operation.

TABLE II.—SUBSTANCES WHICH HAVE BEEN REPORTED TO PRODUCE STRUCTURES RESEMBLING MORPHOLOGIC TUBERCLES WITHOUT CASEATION IN SOME SPECIES*

Bacteria: *Mycobacterium tuberculosis*; *Mycobacterium leprae*; *Malleomyces mallei*; *Pasteurella pestis* and coal dust impregnated with *Bacillus subtilis*; *Pasteurella pseudotuberculosis*; *Brucella abortus*; *Brucella melitensis*; *Pasteurella tularensis*.

Fungi: *Aspergillus*; *Blastomyces*; *Actinomyces*; *Trichophyton*; *Coccidioides* and *Actinomyces asteroides*.

Plants: *Lycopodium* (club moss); finely divided cork and pepper.

Protozoa:

Sporozoa: *Sarcosporidia*.

Spirochetes: *Treponema pallidum*.

Platyhelminthes:

Nematodes: *Ascaris*; *Filaria*.

Trematodes: *Schistosoma mansoni*.

Cestodes: *Echinococcus*.

Chemical and derived substances: mercury; talc; fibrous sericite; powdered dry silica gel; cholesterol esters; oil of turpentine and euphorbium; the lipid, phosphatide or protein extracts of tubercle bacilli; lipid extracts of liver, grass bacilli or colon bacilli, and mineral oils.

*Sarcoid, acne rosacea, and other skin lesions which may represent allergic responses to the tubercle bacilli, and keratinizing squamous cell epithelioma sometimes resemble noncaseous tubercles.

Study on animals. An attempt was made, therefore, to determine whether the crystals could have been adsorbed from the gastrointestinal tract. Six adult white rats were selected for this study. They were fed for 30 days on stock ration plus talc crystals so that 10 per cent of the ration consisted of talc. The diet was then changed so that it contained 20 per cent talc and this ration was fed for 12 days more. There was no change in the bowel habitus and the rats showed no ill effects from the high concentration of talc. They seemed to thrive on it. Polariscopic examination of the stools revealed that they were loaded with talc. Feeding of talc was discontinued after 42 days and the rats were allowed to eat straight stock ration for 9 days so that the talc in the gastrointestinal tract would have a chance to empty out. Then the animals were killed and necropsy performed. Fresh frozen sections were made of all the organs and were examined by means of polarized light.

On opening the abdomen, the peritoneum appeared normal and there was little of note other than a slightly thickened mesentery and marked prominence of the Peyer's patches along the terminal part of the ileum. Sections of the terminal part of the ileum showed segments in which there was infiltration of the villi by lymphocytes and eosinophils (Fig. 7). The connective tissue between the muscularis mucosae and the tunica muscularis showed more birefringence than it nor-

mally does. The muscle layers were normal except for the infiltration of lymphocytes in the regions of vessels and lymphatics. There was moderate hypertrophy of the nerve tracts and ganglionic plexuses. The lesion diminished in the proximal portion of the ileum and both the jejunum and stomach showed little change. Examination of the colon gave negative results.

Birefringent talc could not be found in the intestinal wall or other viscera. The liver was normal except for a few regions in which small local hemorrhages were found. In the tubules of the kidney there was found similar evidence of the rupture of a few capillaries. There was slight early acute glomerulitis (Fig. 8). Polymorphonuclear leucocytes were present in some glomeruli in small numbers and occasionally the lesion had extended and obliterated the tuft which was replaced by a granular mass studded with pyknotic nuclei. There was some hyperplasia of the germinal centers of the spleen (Fig. 9) but the most prominent change was seen in the blood sinuses. These were distended with red blood cells and lymphocytes. The eosinophils were moderately increased. The amount of connective tissue was more than usual. Some areas showed extensive deposits of hemosiderin.

The interpretation of these minimal findings is difficult. The initial dose of talc was intentionally high, yet it was doubled because the rats seemed to thrive on the first dose. Most of the effects may have been produced mechanically by the large amount of talc in the intestinal contents. But talc is not particularly hard. It is softer than the bismuth, calcium, and barium salts that occasionally find their way into the intestinal tract. It was hoped that the local mechanical effects would have cleared up in the 9 days between the last dose of talc and the termination of the experiment. No evidence of birefringent talc was found in the walls or lumen of the gastrointestinal tract. Similarly none was found elsewhere in the body. Probably a longer interval after the last dose of talc would have been more satisfactory. But this much can be gleaned from the experiments. The lesion, whatever its mechanism, was segmental and most prominent in the terminal part of the ileum. This is the site of predilection of many of the granulomatous lesions of the intestines. If the lesion was produced by a colloidal fraction leached from the talc, the inflammatory reaction would be the response anticipated and its locale would be the terminal portion of the ileum. The slight endothelial reaction present in the kidney and to a lesser extent in the spleen and liver was suggestive of the lesions that have been described following

the injection and oral ingestion of fresh silicic acid. The abundance of eosinophils in the inflammatory response is an occasional characteristic of lesions produced by talc. There was no evidence of the absorption of any particles large enough to be visualized by polarized light but colloidal particles are not visible. The rats did not show symptoms or change in bowel habitus. However, the changes in the kidneys suggest that a colloidal fraction of talc may be absorbed and excreted via the kidneys.

ROLE OF TALC IN PERSISTENCE OF FECAL FISTULAS AND RESPONSE OF ILEUM TO INJECTION OF TALC

In a previous report (16) on 408 surgically treated fecal fistulas, it was found that talc, placed in the abdomen during the course of previous operations, had produced talc granulomas in the walls of some of the fistulas. Fifty of the more persistent fistulas, in which there was no apparent cause for the persistence of the fistulas, were selected for detailed microscopic study. In this smaller group, talc was demonstrated in 4 fistulas (8 per cent). Because of the relation of the talc to the inflammatory reaction, and the organization of the fistulas, it was assumed that the talc was a factor in maintaining the fistulas.

In order to test the validity of this assumption and incidentally to study the pathogenesis of talc granuloma, we decided to determine whether talc in the serosa of the bowel would alter the natural tendency of the proximal limbs of isolated loops of intestine to close. It was not the purpose of this work to study the effect of talc alone but of talc plus infection.

The same batch of talc was used throughout this work for uniformity. It was not fresh since it was the variety used in the operating room. A 1 per cent suspension was made up and sterilized. Since the talc was in suspension, the activity was less than that of the dry fresh dust.

Six dogs were subjected to operation under ether anesthesia with aseptic technique. A mid-line abdominal incision was made. About 40 centimeters of the distal portion of the ileum was selected for isolation. Suitable vascular arcades were identified and the marginal vessels were cut between ligatures. The bowel was cut between clamps and the 40 centimeters of ileum with its blood supply intact was isolated. Continuity of the ileum was established by side-to-side anastomosis (Figs. 10 and 11).

The isolated segment of ileum was divided between clamps into two halves 20 centimeters long. Two stab wounds were made through the abdom-

Fig. 1. Talc granuloma in scar of forehead which originally was considered as noncaseous tuberculosis because of the characteristic hard tubercles and extensive fibrosis. Polarized light revealed a wide distribution of talc ($\times 88$; polarizer at $\frac{1}{4}$ extinction to show surrounding lesion).

Fig. 2. Talc granuloma in an inflammatory sinus tract from the abdominal wall. There was extensive fibrosis ($\times 132$; polarizers at $\frac{1}{4}$ extinction to show background).

inal wall on each side of the incision as exits for the two ileal loops thus created. The peristaltic direction was marked carefully. The ends of the loops were brought out through the appropriate stab wounds. The ends of the more proximal of the two loops were brought out to the right (right side of the dog) of the incision (Fig. 12a and b) with proximal end cephalad and distal end 5 centimeters caudad. The more distal of the two loops was brought out to the left of the incision (Fig. 12c and d) in a similar manner again maintaining peristalsis in a caudad direction. The proximal limb of the right loop and the distal limb of the left loop were treated with talc; this procedure thus permitted each dog to act as a control on itself. Two cubic centimeters of the 1 per cent talc suspension was injected subserosally as follows: A syringe attached to a short bevel 27 gauge hypodermic needle was used. Multiple punctures were made in a segment 1 centimeter long of proximal end of right loop (Fig. 11a) and the distal end of the left loop (Fig. 11d). A total of 40 milligrams of talc was used in each dog. A few wheals were raised in the parietal peritoneum near the proximal end of the proximal loop (a in Figs. 11 and 12). Small amounts of talc suspension invariably escaped into the peritoneal cavity. Control punctures were made in the untreated ends of the loops. The abdomen was closed and the four projecting ends of the two loops were fixed to the abdominal wall by two catgut sutures (Fig. 12). The operative trauma was intentionally extensive. This was done in an attempt to reproduce con-

ditions as nearly as possible like those in the cases in which fecal fistulas occurred, for questioning of the patients who had postoperative fecal fistulas had revealed that the original operation was frequently an emergency procedure and there was a stormy postoperative course owing to peritonitis.

Postoperatively all the animals showed signs of peritonitis. Three weeks after operation induration about the intestinal stomas subsided and it was possible to begin observations. Six weeks

Fig. 3. Sarcoid of the gall bladder was suspected at first; actually the tubercles represent a foreign body response to both talc and cholesterol esters. Several cholesterol ester liquid crystals may be seen in the gallbladder; nearer the mucosa there were talc crystals also. Both substances were found in the sentinel lymph node ($\times 97$; polarizer at $\frac{1}{4}$ extinction to show surrounding lesion).

Fig. 4. Talc granuloma found in a gastroenteric stoma dismantled and excised because of malfunction ($\times 117$; polarizer at total extinction).

after operation it was obvious that the treated loops were open and the untreated loops were closing. Although it was anticipated that the distal limb on the right would remain open because of peristalsis, it closed. This probably resulted from the fact that its proximal end had been treated with talc and was not closing. Eight weeks after operation the untreated ends were marked by a firm nodule under the skin, and on the treated ends the stomas seemed stabilized. The open ends had clean everted lips of mucosa.

Fig. 6. Incinerated section under polarized light showing a tubercle around birefringent crystals in the ileum ($\times 110$; polarizer at total extinction).

Fig. 5. This lesion in the ileum on first study seemed to be noncascous tuberculosis. The relation of the birefringent crystals to the reaction and their inclusion in foreign body giant cells and histiocytes suggest that they are the cause of the pathologic picture rather than the result of an inflammatory process. None of these crystals was visible in ordinary light ($\times 48$).

Four of the animals remained ill throughout the study and 2 regained their original activity. One animal was killed 96 days after operation and the others, 140 to 150 days after operation. At necropsy many adhesions to the sites of injection of talc were found. Two of the animals, both of which had been sick, had internal fistulas. These fistulas apparently had caused their chronic illness and loss of weight. One of them had multiple fistulas around the side-to-side anastomosis (Fig. 13). In 4 of the dogs the isolated ileal loops were the same size as the normal ileum but their walls were thickened. In 2 of the dogs the proximal loop, which had received an injection of the talc in the proximal end, was dilated and thickened to four times normal size. The distal ends of all the right loops had closed despite the fact that peristalsis ran in that direction. The closing of the distal ends of these right loops of intestine is probably the best evidence of the effect of talc in the wall of the intestine. Not only did it maintain patency in the end most likely to close but it permitted closure of the end most likely to remain open (Fig. 14). The factor that ordinarily keeps the distal end open is probably the mucus brought down by peristalsis. When proximal end was maintained patent by the talc in its wall, spontaneous closure of untreated distal end was permitted. The closed right distal and proximal limbs were represented by a fibrous cord in the abdominal wall. The mesentery was thickened and matted.

Fig. 7. Infiltration with leucocytes and lymphocytes of the terminal part of ileum of the rats fed talc.

No talc nodules were seen grossly on the peritoneum of these dogs. In the regions in which the talc was placed, however, inflammatory granulation tissue was present. Examination of the other organs did not reveal any abnormalities. The anastomosis in the ileum in each animal was well healed and functioning although 2 animals showed the internal fistulas mentioned. Infection was general and operative trauma extensive.

Frozen sections were made of the organs and they were examined with the aid of polarized light. The mesentery and areas of lymphatic drainage for the sites of injection of talc were examined. No talc was found in these nodes or anywhere else but at the sites of injection or spilling of talc. With the small amounts of talc injected, there was little opportunity for its transport from the site of injection.

Although no visible talc was found to have been transported to the lymphatics of the mesentery there was definite evidence of the extension of the inflammatory reaction. The nodes of the mesentery showed marked hyperplasia with proliferation of the reticulo-endothelial cells of the sinuses such as is seen in mesenteric lymphadenitis. The spleen showed marked hyperplasia of the germinal centers with an increase of eosinophils. There were heavy bands of collagenous connective tissue along the blood vessels (Fig. 15). No birefringent talc was seen in the spleen or the liver. The hepatic lymph nodes were enlarged however.

The intestinal wall at the site of the injection of talc contained chronic granulomatous lesions. The villi were thickened and contained eosinophils,

Fig. 8. The kidney of the rat showing early minimal glomerulitis with hemorrhage and slight infiltration of leucocytes ($\times 176$).

plasma cells, and histiocytes. There was hyperplasia of lymph follicles and muscle elements. The nerve tracts and ganglia in the intestinal wall near the site of injection were enormously hypertrophied and formed large masses. When larger talc particles were found (Fig. 16) in clusters, the lesion consisted of large numbers of foreign body giant cells surrounded by epithelioid leucocytes. The talc crystals distributed in the connective tissue tended to adlineate themselves with fibroblasts and collagen fibers. Many nodules of a

Fig. 9. Slight hyperplasia of the germinal centers in the spleen of a rat. There were areas of congestion, hemorrhage, and deposits of hemosiderin. Many small foreign body giant cells may be seen ($\times 172$).

cellular variety of fibrous tissue were present. These were particularly characteristic of the talc lesion in dogs (Fig. 17). Unlike the silicotic nodule, many fibroblasts were present and some capillaries crossed the nodules. There seemed to be little tendency for this type of fibrous tissue to close off its blood supply and little collagen and no

hyalinization were noted. The connective tissue showed no obvious organization. On examination with polarized light no talc crystals were found in this region but when the section was incinerated, small birefringent specks were found uniformly distributed throughout the connective tissue. The areas of desmoplasia were circumscribed by thin layers of collagenous connective tissue which in turn were surrounded by many lymphocytes. The connective tissue between the tunica muscularis and the muscularis mucosae was highly birefringent. This layer is birefringent in the normal intestine but the magnitude of birefringence was increased in these animals. Sections of ileum in the region injected with talc revealed a picture that resembled strikingly the picture found in regional enteritis.

As a result of this study on isolated loops of intestine together with information derived from the data considered thus far a possible explanation for the chronicity and progression of regional enteritis is as follows: It is known that some foreign bodies while producing a minor reaction themselves tend to sustain the inflammatory response to infection for long periods despite subsidence of the infection. Birefringent crystals have been

Fig. 12. Position of the four emerging limbs of the ileum on the dog's abdomen. Stomas at a and d were treated with talc and were the only ones to remain patent. Peristalsis was caudad in both loops and if talc had not been injected both b and d would have remained patent.

Fig. 15. Section of the spleen of an animal which had received subperitoneal injections of talc. Hyperplasia of the germinal centers is marked and the collagenous connective tissue is increased ($\times 44$).

Fig. 16. Response of the ileum to larger crystals of talc that were injected. The crystals are enclosed by histiocytes. Hypertrophy of the nerves, thickening of the vessel walls, and moderate fibrosis should be noted. In the lower left corner there is an infiltration with lymphocytes ($\times 53$).

ical factors in the foreign body dust and the local region of host tissue are subject to innumerable variations which control the type of reaction. The production of lesions morphologically resembling tubercles may require certain fixed conditions. Epithelioid cells may be derived from monocytes by the phagocytosis of colloidal or finely divided foreign material, with certain

physicochemical characteristics, which does not destroy the cell. It is possible too that it requires a longer time than was allowed in this study, for the development of tubercles in dogs after the injection of talc. An active dry dust may be essential or the type of bacteria in the lesion may modify the lesion.

An early impression that trauma and infection played a leading part in the determination of the morphology of the talc lesion was not completely substantiated. In the same animal, adjacent regions showing extreme variation in the response were found. In some regions, the talc provoked a marked inflammatory response with many foreign body giant cells while in other regions it was found distributed in the connective tissue spaces simply engulfed in histiocytes with little surrounding reaction.

Lesions 3 to 5 days after injection. The immediate reaction to talc was necrosis of the cells in the region of the injection. At this time also bacterial infection was at its height. At the site of injection instead of the leucocytic response which bacteria alone would have produced, all cell outlines were lost and the field was strewn with chromatin debris. Small regions resembling caseous necrosis were found which were surrounded by polymorphonuclear leucocytes and an increased number of eosinophilic elements. An occasional crystal of talc was engulfed by histiocytes. The reaction was uniform at this time and not subject to the variation that was found at later periods. It rep-

Fig. 17. A nodule of a rather cellular type of fibrous tissue produced in the ileum of the dog by the injection of talc crystals. Nerve fibers between the muscle coats are increased and the thickening of the muscular coats is probably brought about by a decrease in the length of the ileum which contributes to the thickening of the intestine. Regional enteritis shows a similar muscular hypertrophy ($\times 62$).

Fig. 18. Lesion in the ileum of the dog 19 days after the subperitoneal injection of talc. The response is inflammatory. Polymorphonuclear leucocytes, lymphocytes, and histiocytes are abundant ($\times 47$).

resented the reaction to the more active talc molecules on the surface of the crystals and those already dispersed in the suspension fluid.

Lesions 19 days after injection. At this phase the nature of the response was determined by the size and distribution of the particles. Although particles of various sizes were distributed uniformly in the suspension at time of injection 19 days later the particles seemed to have been sorted by transportation.

The reaction around small particles up to 3 microns in diameter, about the size range of bacteria, was predominantly inflammatory (Fig. 18). Polymorphonuclear leucocytes, lymphocytes, and histiocytes were numerous. Eosinophils and some plasma cells were present. Lymphocytes were found in large masses. While fibroblasts were present there was no evidence of added fibrous tissue.

When the particles were moderate in size, approximately 3 to 12 microns in diameter, the crystals were engulfed by larger histiocytes. Little surrounding inflammatory response and no polymorphonuclear leucocytes were found. A large percentage of the crystals were parallel to the planes of the connective tissue found in the region. Similarly, the particles in histiocytes were usually situated in the long axis of the cell.

Larger particles of talc, measuring more than 12 microns in diameter, were engulfed by foreign body giant cells. When the particle was too large, only a portion was contained in the foreign body

Fig. 19. Lesion produced by talc in the abdominal wall after 96 days. There is a proliferation of a cellular variety of connective tissue in bundles. The larger crystals in the center are engulfed by foreign body giant cells ($\times 71$).

giant cell. There were no surrounding fibroblasts or leucocytes.

Lesions 96 days after injection. In the dog at this time the talc granuloma was characterized by peculiar desmoplasia and did not resemble granulomas found in man. The desmoplasia consisted of large nodular masses of a cellular type of fibrous tissue (Fig. 19). There was a limited amount of

Fig. 20. Edge of a mature fibrous tissue nodule 140 to 150 days after injection of talc. The fibrous tissue is cellular and the capillaries are abundant. The surrounding connective tissue shows more fibrous and collagenous elements. This response occurs in dogs but in human beings a pseudotubercle forms ($\times 44$).

fibrillar tissue with little apparent arrangement. This fibrillar tissue was surrounded by a thin band of collagenous connective tissue. No visible talc crystals were seen in this nodule of loose connective tissue, but after incineration a dispersed form of talc crystals was found which was not made visible by polarized light in the fresh frozen section. After incineration these fine birefringent specks were easily visible. They were probably the bodies that were seen in brownian movement in the solubility studies.

Although no talc crystals were visible in fresh frozen sections in the nodular masses of loose connective tissue, talc crystals were visible in fresh frozen sections of tissues around the nodules. Large particles were engulfed by foreign body giant cells and the reaction about them was stationary. In the peritoneal adhesions examined, granulation tissue was found which was well vascularized and contained many particles of talc. Lymphocytes, histiocytes and eosinophils filled the regions between the capillary tufts and the fibroblasts were contained in a loose fibrillar tissue. Inflammation seemed to persist at this late date in these adhesions despite the fact that the inflammation in the peritoneal cavity in general had long since subsided. When nerves were found adjacent to the site of injection of the talc, particularly in the intestinal wall, hyperplasia of the nerve fibers and ganglion cells was seen.

Lesions 140 to 150 days after injection. The lesion had not changed from the one found earlier except for an increase in the collagenous connective tissue surrounding the loose fibrous nodules (Fig. 20). The loose fibrous tissue usually contained a few capillaries and occasionally larger vessels were seen crossing into the nodule.

Some of the characteristics of talc granuloma noted in this study of pathogenesis have suggested the use of talc from time to time when well vascularized new tissue is desired. It has been used to provide a parasitic blood supply for the heart and to create adhesions in the pleural space. It may be of value in producing a parasitic blood supply in cases of cirrhosis. In addition to these therapeutic uses of talc, its ability to maintain the patency of fistulas might be of value in establishing intentional biliary fistulas. There are many situations where a firm well vascularized tissue, which will not contract, is desired.

PRODUCTION OF GRANULOMAS BY FOREIGN BODIES WITH EMPHASIS ON TALC GRANULOMA

In view of the widespread use at operations of the dry glove technique which calls for the dusting with talc of gloves used by surgeons it is surprising

that the injurious effects of talc are not seen more frequently. Evidence that the response of various individuals to foreign bodies differs greatly is encountered frequently. Many miners work for years in high concentrations of silica dust without the development of clinical silicosis whereas others show signs of silicosis. When symptoms do appear they usually are noted from 6 to 30 years after first exposure. Fats and oils are constantly being aspirated into the lungs; oil when it is a vehicle for some drug is injected frequently, radiopaque oil often is introduced for diagnostic purposes, and vaselin drains and paraffin have been used extensively for many purposes, yet a granuloma develops only occasionally. While the work on animals has revealed much less variation in the response to foreign bodies from animal to animal, even there the responses differ considerably. Concomitant infection and trauma seem to modify the individual response. The change in the pH of the tissue fluids (which are usually somewhat alkaline) produced by infection, may be a factor in altering the individual's response to foreign bodies.

When particulate insoluble foreign matter is introduced into the body, the initial reaction to the trauma of insertion is inflammatory. Substances which are initially toxic create such cellular proliferation and edema that the substances are shed by the formation of abscess or slough. Particulate substances which produce granulomas first invade the tissues insidiously. The presence of infection may modify events, so that the physicochemical properties of an almost innocuous foreign body can cause a foreign body reaction which in turn results in the pathologic changes of granuloma. The proliferation and phagocytic activity of the histiocytes increase. The purposeful aspect of this process is the provision of a barrier between the constantly changing tissue fluids and the foreign body. This barrier prevents the continuous leaching of the particle. The evidence for this assumption is the fact that if the particle has a jagged end, that end is surrounded first. The small particles are completely engulfed and the larger particles are isolated by many cells which ultimately fuse. In this phase of the process the toxic action of the fraction of the particle leached out within the engulfing cell determines the future course. If the toxic action is lethal, the field will be strewn with the pycnotic vestiges of phagocytic cells. Fresh phagocytes must take up the foreign body anew. If infection is still active, phagocytic activity is less efficient; for when a histiocyte is performing one function, its ability to do others is reduced. The relative strength and

character of each of these factors determine whether the end-result is an abscess, a mass of lymphocytes, plasma cells or histiocytes, an epithelioid reaction with formation of so-called tubercles or fibrosis.

Tubercle bacilli have the peculiar property of acting as foreign bodies or inflammatory organisms at various times in the history of their residence in tissues. In one individual they produce a proliferative lesion and in another an exudative one. As time passes, if the activity of the tubercle bacilli is successfully slowed, an exudative lesion may change to a proliferative one by the increased production of limiting fibrous tissue. When silicosis and tuberculosis coexist, although fibrosis is a prominent feature at certain stages, a change in the physicochemical status of the tissue may permit acceleration of the growth of the tubercle bacilli. In addition, the fibrosis due to silica is so extensive that it interferes with the disposal mechanism of the tissue. Talc does not stimulate the production of fibrous tissue to the extent that silica does but the presence of infection and talc will cause minimal, nonprogressive fibrosis which provides a limiting or restricting barrier. In rare instances talc plus infection will produce a moderate degree of fibrosis. Lesions similar in many respects to talc granuloma result from crystals of cholesterol esters with the formation under suitable conditions of pseudotubercles. These lesions are frequently diagnosed as tuberculosis at first glance. The use of polarized light microscopy makes the cause obvious. A quiescent foreign body reaction may be activated by the addition of infection or trauma. When fatty tissues are involved, infection or trauma may cause the release of irritating free fatty acids and cholesterol esters. These in turn further aggravate the foreign body reaction.

In the silicotic nodule unbridled fibrosis may occur after which contraction of the fibrous tissue creates an avascular nodule. In this avascular nodule basket-weave laminations of collagen at first form discrete nodules. Added infection will induce a conglomeration of these nodules. Hyalinization, which is common as the mass of fibrous tissue increases in size, is accompanied by an increase in the natural silicate in the collagen. Tuberculous lesions show caseation, necrosis, and calcification. The pseudotubercles seen in so-called regional enteritis do not undergo these changes but pyogenic centered tubercles are seen in which the centers are filled with polymorphonuclear leucocytes. Talc, cholesterol esters, and some other foreign bodies produce pseudotubercles which, although they resemble early tubercles, do

not show caseation, calcification, or pyogenic centers. The lesion produced by these foreign bodies seems to be arrested for long periods at the pseudotubercle phase with slight circumscribed fibrosis.

Great damage is caused by birefringent particles which are the same size as bacteria. They are engulfed rapidly by the phagocytes. Inert carbon particles will be engulfed but do not alter the activity of the phagocytes as there is no slow leaching of the particle. Therefore they may enter the blood stream with little injury to be stored innocuously in the storage depots of the bone marrow, spleen, liver, and lymph nodes. The action of silica particles is slow, allowing activity of the phagocytes long enough for them to carry the particles to a more dangerous site, the lymphatic channel. This Trojan-horse stratagem with early blockage of the lymph system explains the progressive nature of the silicotic process. Talc, however, seems to immobilize the phagocyte without destroying it and migration from the original site is limited. Hence most of the lesions produced by talc are circumscribed granulomas, which occasionally are activated after long quiescent periods by infection or trauma. Talc in some cases gets as far as the regional lymph nodes. Since migration of phagocytes containing talc is limited, plaques of talc have been found on the peritoneum where they had been placed accidentally by contact with a glove dusted with talc. There is just enough fibrosis to surround the granuloma. This lesion tends to remain stationary for a long time. The vascular supply to the small nodule is good, as there is slight tendency for proliferation of fibrous tissue which in contraction would diminish the blood supply. Asbestos ground to particles of from r to 3 microns in diameter causes lesions similar to the granulomas produced by talc.

COMMENT AND CONCLUSIONS

Evidence is presented to show that the tissue damage caused occasionally by talc is a heavy price to pay for the preservation of a pair of rubber gloves. Granulomatous lesions of the peritoneum, draining sinuses, scar nodules, and malfunctioning intestinal stomas were found at secondary operations. Polarized light microscopy was of great value in identifying talc crystals and in studying the pathogenesis of talc granuloma. It was our impression that talc granulomas would be recognized more frequently if there were greater use of polarized light microscopy and this study substantiated this hypothesis.

Talc implanted around intentionally created fistulas in dogs caused persistence of the fistulas.

A characteristic loose fibrous tissue lesion is produced by talc in dogs, whereas tissues of human beings react by forming pseudotubercles.

Lycopodium powder has been removed from use in the operating room. Talc also must go.¹ Foreign bodies of this type have no place at the operating table. Lubricating oil on instruments, petrolatum, and iodoform are injurious to some individuals. Even the lint left by pressure from dry gauze sponges may be found in adhesions following multiple operations. Synthetic materials which do not leave lint behind may be available presently. In some cases these minor factors cause unnecessary postoperative discomfort.

¹Following the suggestion of Seelig, Verda, and Kidd we have been using potassium bitartrate at the Mayo Clinic with satisfaction in two operating rooms for 24 months. While this substance may not preserve rubber gloves as long as talc does, gloves are usually discarded because of perforations rather than wear. It is expected that a starch that can be autoclaved soon will be available which will be superior to talc.

SECTION OF THE VAGUS NERVES TO THE STOMACH IN THE TREATMENT OF PEPTIC ULCER

THE important rôle of the nervous system in the production and maintenance of chronic ulcers in the stomach and duodenum has been suspected for many years. Many physicians have called attention to the high incidence of ulcers in individuals whose occupations subject them to continuous mental strain, worry and anxiety, and the tendency for exacerbations to occur during periods of emotional stress. The relatively high incidence of peptic ulcer in the armed services during the war may be, in part, due to similar causes. Direct evidence implicating the central nervous system was supplied by Cushing, who reported a greater occurrence of acute perforating ulcers of the stomach and duodenum in patients recovering from certain operations on the brain than mere coincidence could allow. These findings

have been confirmed by others and indicate a definite hazard in neurologic surgery.

How can disturbances in the brain affect the stomach and produce a progressive perforating ulcer? While the gastrointestinal tract possesses a true local automatism, its tonus, motility, blood supply, and secretory activity are greatly modified by efferent impulses in the vagi and sympathetics. To a certain limited extent, these nerves exert antagonistic effects and the end-result represents a balance of opposing mechanisms. Excessive activity of the sympathetic fibers might, on theoretical grounds, lead to spasm of the cardia, atony of the stomach, spasm of the pylorus, and decrease in the tonus and motility of the intestines. No changes in the secretion of gastric juice would be expected but generalized or local vasoconstriction might result. The idea that peptic ulcer is due to local anemia of an area of the gastric mucosa as a result of embolism or vasospasm receives continued consideration. Cushing suggested that the ulcers observed by him might have such an origin. In recent years an attempt has been made in France to treat peptic ulcer by dividing the splanchnic nerves and excising the first two lumbar sympathetic ganglia. Relief of the ulcer distress was reported but the operation seems now to have been abandoned. The relief obtained could, of course, be due to interruption of sensory fibers conveying sensations of pain from the stomach. No convincing evidence has been presented that an excessive or abnormal activity of the sympathetic nervous system exists in ulcer patients, and the experimental evidence is for the most part against this point of view.

Excessive activity or hypertonus of the vagus efferent fibers might be expected to cause a relaxation of the cardia and pylorus, an increase in the motility and tonic constriction of the stomach, and an increase in the secretion of gastric juice. Gastric hypermotility in most ulcer patients has long been recognized and of late, evidence has accumulated indicating that an excessive continuous secretion of gastric juice occurs in the empty stomach in the absence of the usual stimulus of food. Both the hypermotility and hypersecretion are abolished by complete section of the vagus nerves to the stomach indicating that they are neurogenic in origin. The characteristic ulcer distress is also relieved and that this relief is not due to interruption of sensory fibers is indicated by the fact that the distress can be produced again by the instillation of a solution of hydrochloric acid into the stomach. Objective gastroscopic and x-ray evidence of the healing of large ulcer craters in the stomach, duodenum, and perhaps most of all, in gastrojejunal stomas after vagus section provides convincing evidence that this procedure corrects those factors that maintain chronicity and progression in these lesions. Since both motility and secretion are reduced, it is not possible to decide from this evidence alone which is the more important in the pathogenesis of the disease. It is in this connection that the data from the experimental laboratory are of decisive importance and the answer is clear. Pure undiluted gastric juice can digest away the normal mucosa of the stomach, duodenum, or jejunum and produce a typical progressive ulcer. Under normal conditions the gastric juice is diluted and buffered by food and the alkaline duodenal secretions. When an excessive secretion of gastric juice occurs in the empty stomach, the buffering effect of food is absent and the neutralizing capacity

of the duodenal secretions is overcome. The gastric content then approaches pure gastric juice in free acidity and pepsin concentration and that area of the gastric or duodenal mucosa which is most exposed or least resistant first succumbs. An ulcer forms, progresses, and persists so long as exposure to relatively pure gastric juice continues. Therapy accordingly should be directed toward reducing the volume and acidity of the night secretion. The finding that the excessive continuous secretion in the fasting stomach of ulcer patients is neurogenic in origin constitutes the physiological basis for vagus section as a method of treatment. At the present writing, 90 patients have been operated upon by this method in this clinic. Keith Grimson at Duke University, Francis Moore in Boston and Dixon and Clagett at the Mayo Clinic have also reported similar series. So far, there appears to be general agreement concerning the immediate and long continued relief of ulcer distress. For the most part, the period of observation has been too short to permit a final evaluation of the method and the question of ultimate regeneration of the divided vagi remains undecided. The first 12 patients operated upon here a little over three years ago are still well, take no medication, and are under no dietary restrictions. The night secretion of gastric juice is still within the normal range and tests of gastric secretion by the sham meal and insulin hypoglycemia show that regeneration of secretory fibers in the vagi has not yet occurred.

These findings provide strong support to the concept of ulcer as a psychosomatic disease, this term being used merely to indicate that emotions and mental activity of certain types play a dominant rôle in the pathogenesis. The central nervous system disturbance causes ulcers by producing a hypertonus in the secretory and motor fibers

in the vagus nerves. While the severing of these nerves prevents nervous tensions of various kinds from affecting the stomach, it cannot be considered the final answer to the ulcer problem. Perhaps this may lie in adjusting the individual to his work and environment so that these tensions do not arise. The possibilities of psychotherapy in ulcer ought to be re-explored, and the volume and acidity of the continuous night secretion of gastric juice used as an objective quantitative measure of the effect of the treatment. Such data would probably be more impressive to the surgeon than the most subtle manipulation of a terminology he never fully understands.

LESTER R. DRAGSTEDT.

BENIGN STRICTURES OF THE BILE DUCT

STRICTURE of the common or hepatic bile duct most often follows clamping, ligation or excision of the duct during cholecystectomy. Sir James Walton has said "Every removal of a gall bladder, easy though it may seem, is fraught with very great danger, and one small error may convert a patient with a mild disability into one in immediate danger of death or of prolonged misery, and many operations, which at best may only give an incomplete life." The common duct will not be injured if it is clearly seen. The first necessity is adequate exposure with accurate definition of the junction of the hepatic, cystic, and common ducts before anything is clamped or cut. If this rule is followed, most of the hazards are eliminated. Injury occurs with inadequate exposure, inflammation or impaction of stones that shorten the cystic duct, strong traction on the gall bladder that tents up the common duct, anatomic abnormalities that confuse the relations, and blind efforts to control bleeding.

If the surgeon discovers a damaged or severed common bile duct, it should be repaired immediately for it is never easier to do later. The two ends of a divided duct should be united by end-to-end anastomosis. If a T-tube is used, the vertical limb should not come out through the suture line but rather above or below it. A duct that has been crushed by a clamp should be allowed to heal over a tube. If it is badly macerated, the devitalized tissue may be excised and an end-to-end anastomosis done.

The end-result of unrepaired common duct injury is biliary fistula or stricture with its devastating sequelæ. Small strictures are not so serious for they may often be successfully treated by plastic repair or by excision and end-to-end anastomosis. The real problem concerns those who have extensive stricture or loss of the duct, often complicated by repeated, fruitless attempts at repair and usually associated with anemia, hypoproteinemia, infection, and liver damage. These may tax the fortitude, patience and ingenuity of those who seek to repair them. No single method is applicable to all cases. In general, two methods of attack have been used; either anastomosis of the duct to the intestine or reconstruction of the duct. Of the former, anastomosis of the duct to the duodenum has been used most frequently but only 23 per cent have a successful end-result (Eliot). The Roux Y type of choledochojejunostomy, popularized by Whipple, is a more physiological intestinal anastomosis since the antiperistaltic loop of jejunum prevents reflux of intestinal contents into the biliary tract.

It appears desirable, whenever possible, to restore the normal anatomical arrangement of the part for few surgical procedures improve on nature. For this reason, even with extensive loss or stricture, efforts should be made to reunite what remains of the duct. Such a

union may be possible only with tension on the suture line which permits reformation of the stricture. To prevent stricture the duct should heal over a tube which holds it open during repair. Dissatisfaction with the tissue irritation and fibrosis caused by rubber led to the use of vitallium for this purpose. Vitallium was selected because of its lack of tissue reaction, its smooth surface which did not attract concretions and its high tensile strength which permitted a thin wall with maximum lumen. Tantalum also has these characteristics and is more malleable but it cannot be welded, so no anchoring flange can be attached to it. Plastics were discarded because most of them are tissue irritants. Vitallium tubes have the disadvantage of being so hard that they cannot be altered, at the time of operation, to meet the needs of every situation nor is it possible for them to be removed except by an operative procedure.

Recently, 226 cases of the use of vitallium tubes were collected from a group of surgeons and the results studied. The outcome was satisfactory in 80 per cent of the cases when

the tube was used for the reconstruction of the duct. Plugging of the tube occurred in 11 per cent and was the commonest cause of failure. This plugging may be diminished by using bile salts postoperatively but metabolic changes and infection make it difficult to eliminate occlusion of the tube completely. Anastomosis of the duct to the duodenum over a vitallium tube gave 58 per cent satisfactory results. The tube passed into the intestine in 38 per cent of the cases. This sequela is to be expected for no amount of anchoring will prevent the loosening of the tube. The results of Whipple's Roux Y anastomosis are still better for it is a more physiological operation.

The results enumerated are a real improvement over past experience. They are not perfect and one may question if perfection can be attained under the difficult circumstances encountered in these cases. The most profitable direction for efforts in the future would be the training of surgeons to avoid injury to the bile ducts. Until this is realized the search must continue for improvement in our present techniques and methods.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

NO one who is interested in the surgery of the upper extremity will fail to secure stimulating and helpful ideas from a careful reading of Dr. Steindler's *Traumatic Deformities and Disabilities of the Upper Extremity*.¹ In this volume of almost 500 pages after a general discussion of traumatic disabilities of the upper extremity the author considers in turn disabilities of the shoulder girdle and arm (140 pages), of the elbow joint (90 pages), of the forearm and wrist (100 pages), and of the hand and fingers (75 pages).

One's first impression is of the serious and thoughtful consideration the author brings to bear on the various problems he discusses. For example (page 4), "An identical fracture of the radius may result in one case in a skeletal disalignment without any secondary impairment of the soft structures, in another case there may be no skeletal disalignment but a great deal of involvement of the soft tissues; in a third case a traumatic arthritis will develop, and in a fourth case Sudeck's atrophy on angioneurotic basis may be the principal factor of the disability." It is easy to recognize the obvious factors involved in a given problem. Steindler constantly emphasizes the importance of searching for and recognizing all the pathological factors involved if one is to solve the problem successfully.

The second impression is of the frank and objective manner in which the author attempts to evaluate the results he has obtained from the various procedures he has carried out. One must feel a very real respect and admiration for workers who attempt to evaluate the final results of the methods they have utilized, and who state them honestly. It is easier to portray only the good results and omit the failures and the reasons for their occurrence.

The section on the shoulder girdle and arm is the longest and most complete. After emphasizing the vulnerability of the shoulder girdle because of its connection to the thorax almost solely by muscle masses the author discusses in turn the acromioclavicular articulation and its dislocation, the sternoclavicular articulation and the shoulder joint and its dislocations. The various procedures advocated for the correction of recurrent dislocation are carefully described and the indications for each pointed out. The Nicola operation and the Henderson operation have proved most successful and have been used in the majority of cases.

Fractures of the clavicle followed by nonunion, fractures of the scapula, of the upper end of the

humerus—neck and tuberosities, traumatic arthritis of the shoulder joint, and fractures of the humeral shaft are discussed with unusual completeness. In reading the illustrative case reports one is constantly impressed with the variety and extent of the author's experience, and particularly with the complicated and difficult cases of bone injury—of scapula, humerus, elbow, and forearm—that have come under his care.

Consideration of injuries of the musculospiral nerve, axillary nerve, and of the brachial plexus associated with fractures and dislocations of the humerus, rupture of supraspinatus and biceps tendons, and contractures due to burns completes the section which is devoted to conditions of the shoulder girdle and arm.

Traumatic disabilities of the elbow joint, of the forearm and wrist and of the hand and fingers are taken up in turn with somewhat diminishing emphasis. The complications resulting from fractures and dislocations about the elbow joint, flexion and extension block, nerve injuries and Volkmann's ischemic contracture are discussed in helpful detail. Here again one is impressed with the difficulty and complexity of many of the cases presented, and the conservative attitude which characterizes the author's approach to their treatment. In the treatment of Volkmann's contracture the best results have been obtained by conservative treatment, and, in cases of severe deformity, when conservative treatment has failed, by resection of a part of the carpus and shortening of the extensor tendons. The author believes that there are few indications for detaching the flexor tendons from the medial epicondyle or for shortening of the bones of the forearm.

Nonunion following fracture of both bones of the forearm, radioulnar synostosis, fracture of the ulna with dislocation of the head of the radius, complicated fractures of the lower end of the radius, fractures of the scaphoid, dislocation of the semilunar, Kienbock's disease and Sudeck's atrophy, tendon transference in cases of irreparable musculospiral injury—are all considered in turn, and the treatment illustrated with case reports, diagrams and x-ray films. One can think of none of the many conditions arising from injury of forearm and wrist which has been omitted from consideration.

In the disabilities affecting the hand the chief emphasis has been placed on fractures and dislocations of metacarpals and phalanges and on tendon and nerve injuries. The author's operation and Bunnell's operation for thenar palsy are carefully described and illustrated. Certain procedures concerning which the surgeon with limited experience might

¹THE TRAUMATIC DEFORMITIES AND DISABILITIES OF THE UPPER EXTREMITY. By Arthur Steindler, M.D., F.A.C.S. In collaboration with John Louis Marxer, M.D. Springfield, Ill.: Charles C Thomas, 1946.

well be in doubt, for example, cup arthroplasty at an interphalangeal joint, and artificial methods for reforming tendon sheaths, are described, but the reader is left in doubt as to the author's opinion as to their value and usefulness.

Throughout the entire volume diagrams, photographs, and reproductions of x-ray films help to illustrate the text. The drawings are not always easy to interpret, sometimes they are almost "impressionistic" (Figs. 386, 387). In some instances the addition of legends would help to avoid confusion in their interpretation.

It is obvious that in reviewing a volume which touches upon so many conditions and covers such a wide field one can do little more than point out its purpose and scope. It deserves high praise, and constitutes a record of achievement that will serve both as an example and a highly useful guide to every surgeon confronted with similar problems.

STIMMER L. KOTI

THE volume entitled *Medical Services by Government* by Dr. Bernhard J. Stern, comprising 253 pages, is published by The Commonwealth Fund and is one of the studies of the New York Academy of Medicine Committee on Medicine and the Changing Order. It presents in historical perspective a comprehensive summary of the complex and expanding field of government medical services, federal, state, and local. It should be of interest to those who like to discuss the subject of state medicine which is such a popular pastime at medical meetings nowadays because it contains a great wealth of factual material bearing on this subject. From this book one gets the impression that the establishment of the doctrine of government responsibility for medical care is a *fait accompli*; that all that is left is a matter of methods and mechanics of organization. PRELIMINARY PROGRAM FOR THE 1946 CLINICAL CONGRESS IN CLEVELAND—DECEMBER 16 TO 20

UNDER the direction of the Board of Regents, plans are proceeding for the thirty-second annual Clinical Congress, to be held in Cleveland, December 16 to 20, with headquarters at the Cleveland Public Auditorium and at the Statler and Cleveland hotels. The Auditorium is an impressive, well designed building. Its Arena, Music Hall, Little Theater, Ballroom, and other large halls, provide exceptional facilities, so that most of the activities of the Congress, except the clinical program, will be housed in it.

The program of the Congress in general will be focused upon the many medical and surgical problems connected with important postwar advances, including rehabilitation of veterans.

CLINICAL PROGRAM

The surgeons of Cleveland have appointed an executive committee, with Dr. Thomas E. Jones as chairman, and Dr. John W. Holloway as secretary. The committee with the aid of a representative in each hospital is now preparing a preliminary clinical program. This will consist of operative and nonoperative clinics and demonstrations that will provide a comprehensive showing of their clinical activities in all departments of surgery at Western Reserve University School of Medicine and the approved hospitals of Cleveland. Under the leadership of this committee, a varied program of interest to general surgeons and all surgical specialists is assured for the 1946 Congress.

GENERAL ASSEMBLY

The Clinical Congress will open with a general assembly in the Music Hall of the Cleveland

EXECUTIVE COMMITTEE

THOMAS E. JONES <i>Chairman</i>	SAMUEL O. FREELANDER
JOHN W. HOLLOWAY <i>Secretary</i>	C. LEE GRABER

Woman's Hospital	ERNEST COX
Veterans Hospital	DR. PARTINGTON <i>Chief Surgeon</i>

Public Auditorium at 10:00 o'clock on Monday morning. Dr. W. Edward Gallie, President of the College, will preside at this meeting which will be the opening session of the twenty-fifth annual Hospital Standardization Conference. Doctor Gallie will discuss the Hospital Standardization program of the College, especially as it affects the hospitals of Canada. Dr. Irvin Abell, Chairman of the Board of Regents, will then report on the progress of the 1946 Hospital Standardization

survey, final results of which, including the Approved Lists of hospitals, cancer clinics, and approved hospitals for graduate training in surgery, will be announced at the end of the year.

The remainder of the Monday morning session will be devoted to talks by medical and hospital authorities on advances in medicine and surgery as they affect the postwar hospital, with particular consideration of their relation to the Hospital Standardization program.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening in the Music Hall of the Auditorium. The officers, regents, and honorary guests will participate in the processional. Dr. W. Edward Gallie, President of the College, will preside. The address of welcome will be given by Dr. Thomas E. Jones, Chairman of the Executive Committee, foreign guests will be introduced, and Doctor Gallie will deliver the Presidential Address. An inaugural ceremony will be held for the incoming officers: President, Dr. Irvin Abell of Louisville; First Vice-President, Dr. Leland S. McKittrick of Boston; Second Vice-President, Dr. F. Phinizy Calhoun of Atlanta.

The first Martin Memorial Lecture will be a feature of the Presidential Meeting this year. Dr. Edward D. Churchill of Boston has accepted the invitation to give this lecture. The lectureship was established upon motion of the Board of Regents at its midyear meeting on April 1, as a memorial to both Dr. Franklin M. Martin and Mrs. Martin. The founder of the College and of SURGERY, GYNECOLOGY AND OBSTETRICS, was joined by his wife in making the College the beneficiary at their deaths of the Journal, together with its physical plant operated by the Surgical Publishing Company of Chicago, of which they were the owners. Doctor Martin died in 1935 and Mrs. Martin in 1945.

The Martin Memorial Lecture, to be given annually during the Clinical Congress, and dealing with a scientific subject of the author's choosing, supplants the Annual Oration in Surgery.

CONVOCATION

The Convocation will be held on Friday evening. It will open with a processional of officers, regents, governors, and initiates. The President, Dr. Irvin Abell, will preside, confer the honorary fellowships, and present the candidates for fellowship.

An Assembly of Initiates will be held at 10:30 on Friday morning in order to instruct them in the Convocation procedure and other matters.

On this occasion the initiates will sign the fellowship roll.

Several hundred surgeons who have been received into fellowship *in absentia* during the war years in which no Convocation was held, will be added to the number of initiates for the current year who will be present to participate in the initiation ceremonies. The Convocation and in fact the meetings throughout the Congress will be occasions for reunion with many Fellows who have recently returned from service with the military forces.

SCIENTIFIC SESSIONS

General Surgery

Eminent surgeons and specialists, recognized as authorities in their fields, will address the scientific sessions, to be held on Tuesday, Wednesday, and Thursday evenings. These will be conducted as symposia, and the subjects for the three nights will be as follows: Tuesday, "Care of the Patient Before and After Operation"; Wednesday, "Venous Thrombosis and Prevention of Pulmonary Embolism"; and Thursday, "Antibiotic and Chemotherapeutic Agents in Surgery." The annual Fracture Oration will be included in the Wednesday evening program.

Two major panel discussions will be held every afternoon except Thursday when the first panel will be omitted because of the annual meeting of the Fellows.

A symposium on fractures and other traumas will be held on Tuesday afternoon, and a symposium on cancer on Wednesday.

Concurrent panel discussions are also planned on Friday afternoon for each of the following specialties: plastic surgery, thoracic surgery, urology, neurological surgery, orthopedics, and obstetrics. Outlines of the programs are published in succeeding pages.

Ophthalmology and Otorhinolaryngology

Ophthalmology panel discussions will be held Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock on, respectively, "Retinal Detachment," "Glaucoma," and "Keratoplasty." On Tuesday evening at 8:00 o'clock there will be a symposium on "Orbital Reconstruction Including Prosthesis." On Thursday evening a symposium is planned on "Recent Advances in Ophthalmology," with presentation of the following subjects: "Surgical Applied Anatomy in Eye Surgery"; "Visual Field Defects Due to Head Injuries"; "The Management of Non-Magnetic Intraocular Foreign Bodies"; and "The Treatment of Strabismus in Children."

Otorhinolaryngology panel discussions will be held Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock on, respectively, "Treatment of Meniere's Disease," "Osteomyelitis of the Skull," and "Rehabilitation of the War Deafened." On Tuesday evening at 8:00 o'clock there will be a symposium on "Treatment of Deafness" and on Thursday evening a symposium on "Surgery of the Nasal Accessory Sinuses."

Of interest to ophthalmologists, otorhinolaryngologists, and other surgeons will be a symposium to be held on Wednesday evening at 8:00 o'clock on "Plastic Surgery of the Head and Neck."

FORUMS ON FUNDAMENTAL SURGICAL PROBLEMS

The Forums on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday, and Friday mornings. Included in them will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned, but questions and comments will be invited. Especially keen interest is expected in these sessions this year because of the accumulation of the results of 5 years of work since the last Clinical Congress. Dr. Owen H. Wangensteen of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the forums, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

HOSPITAL CONFERENCE

The opening General Assembly on Monday morning in which both surgeons and hospital representatives will participate has been mentioned previously. The afternoon conference on Monday will be concentrated upon current problems and the outlook for the future in nursing service.

The Tuesday morning conference will be centered upon discussion of management techniques as they affect standards of hospital service. The Tuesday afternoon session will consist of a panel discussion of training and other personnel problems in specific fields, such as dietary, laboratory, x-ray, pharmacy, physical and occupational therapy, medical records, medical social service, and employe relations in small hospitals.

The Wednesday morning conference will have

as its main theme the importance of assuring high standards of care to the community and patients through providing in the general hospital facilities for all types of illness. The subject will be discussed from the standpoint of psychiatric, tuberculous, cancer, chronically ill, and convalescent patients. The Wednesday afternoon meeting will be a panel discussion on the responsibility of the administrative staff in dealing with common emergency procedures.

The Thursday morning conference will revolve around the physical plant of the hospital and the importance of improvement and modernization in raising standards of care of the patient. New mechanical and technical developments will be presented. The afternoon conference will discuss the hospital as the health center of the community, with consideration of the effects of this concept upon hospital public relations and upon the progress of preventive medicine and public health.

An evening conference will be held at 7:30 o'clock on Tuesday. This will be devoted to discussion of the responsibilities of trustees, and members of governing boards will be especially invited to attend and to participate. A conference will be held on Wednesday evening also. This will be a round table conference on responsibilities of hospital administrators, and the preparation which is necessary to enable them to cope successfully with the wide range of administrative problems. The discussion of these problems will interest all hospital personnel.

ANNUAL MEETING OF FELLOWS

The annual meeting of the Governors and Fellows will be held on Thursday afternoon at 1:45. There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization, and to learn how it has not only raised the professional and ethical standards of surgery, but has also promoted good hospitalization and general improvement in the practice of medicine in the United States and Canada. Each Fellow has a personal part in this work and may extend the influence of the College materially in his local community. Hospital Standardization alone offers him unlimited opportunity to provide better medical care for his patients in the hospital in which he works through continuous progress in applying the principles of the Standard which insure the best care of the patient.

Every Fellow will want to attend this important meeting, at which reports will be presented on financial affairs; Hospital Standardization; Graduate Training in Surgery; Medical Motion Pic-

tures; Publications; Public Relations; Library and Literary Research; the work of the state and provincial credentials committees, committees on applicants, and the Committee on History Reviews; Sectional Meetings, 1946; and the Department of Clinical Research, including cancer clinics, Medical Service in Industry, the Committee on Cancer, and the Committee on Fractures and other Traumas. Dr. Abell will report on administration of the College, staff changes, and retirements, and Dr. Arthur W. Allen, Vice-Chairman of the Board of Regents will discuss "Fellowships, Obligations and Opportunities."

STATE AND PROVINCIAL EXECUTIVE, CREDENTIALS AND JUDICIARY COMMITTEES

On Wednesday morning from 9:00 to 12:00 o'clock the State and Provincial Executive, Credentials, and Judiciary committees will meet to discuss their respective activities.

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily in the Little Theatre. These are a much appreciated feature of the Clinical Congress. Despite the decrease in production of such films during the war period, a surprising number of new pictures on varied subjects are being received by the American College of Surgeons for review.

Both sound and silent, standard and color films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be held in the Cleveland Public Auditorium. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, pharmaceuticals, and publishers of medical books will be represented in the exhibition. The technical exhibits will demonstrate many of the newer features learned from our experience in the war. Surgeons and hospital people will have opportunities to inspect the latest products of industries which help to improve their service.

ADVANCE REGISTRATION

The hospitals of Cleveland afford accommodations for a considerable number of visiting surgeons. However, in order to insure against overcrowding, attendance at the Congress will be limited to the number that can be comfortably accommodated at the meetings and also by accommodations in the hotels. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

Fellows of the College whose dues are paid to December 31, 1945, initiates of the classes of 1942, through 1946, and Fellows in military service will not be required to pay a registration fee for the Clinical Congress in Cleveland. Checks that have already been sent for the New York Congress are being returned. For endorsed junior candidates the fee is \$5.00. Surgeons, not Fellows, who attend as invited guests of the College, will pay a registration fee of \$10.00.

CLEVELAND HOTELS AND THEIR RATES

Although the hotel situation in Cleveland seems more favorable than in many other cities, it is nevertheless essential to make reservations as far in advance as possible. Following is a list of the principal hotels:

	No. of Rooms	Rate
The Alcazar, Surrey and Derbyshire Roads	200	\$3.00 up
Hotel Alorton, E. 15th St. & Chester Ave.	600	2.65 up
Hotel Auditorium, E. 6th & St. Clair Ave.	300	2.00 up
Belmont Hotel, Euclid Ave. at E. 40th St.	200	2.00 up
Hotel Bolton Square, Carnegie at E. 89th St.	300	2.50 up
Carter Hotel, 1012 Prospect Ave.	600	4.00 up
Hotel Cleveland, Public Sq. & Superior Ave.	1,000	3.00 up
Fenway Hall Hotel, Euclid Ave. at Univ. Circle	400	3.00 up
The Hollenden, Superior Ave. at E. 6th St.	1,000	3.00 up
Lake Shore Hotel, 12506 Edgewater Dr.	450	3.50 up
New Amsterdam Hotel, Euclid Ave. at E. 22nd St.	300	2.00 up
Hotel Olmsted, E. 9th St. & Superior Ave.	250	3.00 up
Park Lane Villa, E. 105th & Park Lane Ave.	400	3.00 up
Sovereign Hotel, 1575 E. Blvd.	300	2.50 up
Hotel Statler, Euclid Ave. at E. 12th St.	1,000	3.00 up
Tudor Arms Hotel, Carnegie at E. 107th St.	200	3.50 up
Wade Park Manor, E. 107th & Park Lane	400	3.50 up
The Westlake, Blount St., Rocky River..	400	3.00 up

CLINICAL CONGRESS PROGRAM IN BRIEF

UNLESS OTHERWISE DESIGNATED, THE MEETING ROOMS LISTED ARE IN THE CLEVELAND AUDITORIUM

Monday

- 10:00 General Assembly for Surgeons and Hospital Representatives, Music Hall
 1:30-3:00 Panel Discussion, Music Hall
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Ballroom
 1:00 Surgical Film Exhibition (General), Little Theatre
 3:30-5:00 Panel Discussion, Music Hall
 8:00 Presidential Meeting, Music Hall

Tuesday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 10:00 Hospital Conference, Ballroom
 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 9:30-12:00 Forum on Fundamental Surgical Problems, Music Hall
 10:00 Surgical Film Exhibition (General), Little Theatre
 11:00 Panel Discussions
 Ophthalmology, South Hall A
 Otorhinolaryngology, South Hall B
 1:30-3:00 Panel Discussion, Music Hall
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Club Room B
 2:00 Symposium on Fractures and Other Traumas, Ballroom
 2:00 Surgical Film Exhibition (General), Little Theatre
 3:30-5:00 Panel Discussion, Music Hall
 7:00 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 7:30 Hospital Conference—Trustees, Ballroom, Hotel Statler
 8:00 Symposium, General Surgery, Music Hall
 8:00 Symposium, Ophthalmology, South Hall A
 8:00 Symposium, Otorhinolaryngology, South Hall B

Wednesday

- 8:00 Meeting of Cancer Committee, Tavern Room, Hotel Statler
 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Hospital Conference, Ballroom
 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 9:30-12:00 Forum on Fundamental Surgical Problems, Music Hall
 10:00 Surgical Film Exhibition (General), Little Theatre
 State and Provincial Committees:
 9:30 Judiciary Committees
 10:00 Executive Committees
 10:30 Credentials Committees and
 Committees on Applicants
 11:00 Panel Discussions
 Ophthalmology, South Hall A
 Otorhinolaryngology, South Hall B
 12:00 Meeting of Board of Governors, Lattice Room, Hotel Statler
 1:30-3:00 Panel Discussion, Music Hall
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Symposium on Cancer, Ballroom
 2:00 Surgical Film Exhibition (General), Little Theatre

- 2:30 Hospital Conference, Club Room B
 3:30-5:00 Panel Discussion, Music Hall
 6:00 Vandyck Reunion Dinner
 7:00 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 7:30 Hospital Conference—Administrative Problems, Club Room B
 8:00 Symposium, General Surgery, Music Hall
 8:00 Symposium, Ophthalmology and Otorhinolaryngology, South Hall A

Thursday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Hospital Conference, Ballroom
 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 9:30-12:00 Forum on Fundamental Surgical Problems, Music Hall
 10:00 Surgical Film Exhibition (General), Little Theatre
 11:00 Panel Discussions
 Ophthalmology, South Hall A
 Otorhinolaryngology, South Hall B
 1:30 Adjourned Meeting, Governors, Music Hall
 1:45 Annual Meeting, Fellows, Music Hall
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Ballroom
 3:00 Panel Discussion—Graduate Training in Surgery, Club Room B
 3:30-5:00 Panel Discussion, Music Hall
 3:30 Surgical Film Exhibition (General), Little Theatre
 3:30 National and Regional Fracture Committees, Club Room C
 4:00 Committee on the Library
 7:00 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 8:00 Symposium, General Surgery, Music Hall
 8:00 Symposium, Ophthalmology, South Hall A
 8:00 Symposium, Otorhinolaryngology, South Hall B

Friday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), Little Theatre
 9:30-12:00 Forum on Fundamental Surgical Problems, Music Hall
 10:00 Surgical Film Exhibition (General), Little Theatre
 10:30 Assembly of Initiates, Ballroom
 1:30-3:00 Panel Discussion, Surgery of the Stomach, Music Hall
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00-4:00 Panel Discussions
 Obstetrics, South Hall A
 Plastic Surgery, Club Room
 Neurological Surgery, Club Room
 Thoracic Surgery, South Hall A
 Urology, South Hall C
 Orthopedic Surgery, Club Room
 2:00 Surgical Film Exhibition (General), Little Theatre
 3:30-5:00 Panel Discussion, Surgery of the Stomach, Music Hall
 8:00 Convocation, Music Hall

EVENING SYMPOSIA

GENERAL SURGERY

Tuesday, 8:00 p.m.

Care of the Patient before and after Operation

Fluid and Electrolyte Balance. CARL MOYER, Eloise, Michigan.

Nutritional Preparation of the Substernal Risk Patient. RICHARD L. VARCO, Minneapolis.

Use of Blood and Blood Substitutes. JOHN D. STEWART, Buffalo.

Blood Transfusion Problems, with Special Reference to the Rh Factor. ALEXANDER S. WIENER, Brooklyn.

Safe Conduct of the Patient Through Operation. OWEN H. WANGENSTEEN, Minneapolis.

Wednesday, 8:00 p.m.

Venous Thrombosis and Prevention of Pulmonary Embolism

Interruption of Deep Veins. ARTHUR W. ALLEN, Boston.

Sympathetic Nerve Block. ALTON OCHSNER, New Orleans.

Anticoagulants. D. W. GORDON MURRAY, Toronto.

Fracture Orations

Modern Methods in the Treatment of Fractures. EDWIN W. RYERSON, Chicago.

Thursday, 8:00 p.m.

Antibiotic and Chemotherapeutic Agents in Surgery

Pathologic Physiology of Surgical Infections. JOHN S. LOCKWOOD, New Haven.

Penicillin—Its Use in Surgery and Influence on Earlier Types of Chemotherapy. WILLIAM A. ALTEMEIER, Cincinnati.

Streptomycin. HORTON C. HINSHAW, Rochester.

Correlation of the Use of Antibiotic and Chemotherapeutic Agents with General Principles of Surgery.

CLAMP LYONS, New Orleans.

OPHTHALMOLOGY

Tuesday, 8:00 p.m.

Orbital Reconstruction Including Prosthesis

Acrylic Prosthesis. A. D. RUEDEMANN, Cleveland.

Basket Implant. NORMAN L. CUTLER, Wilmington.

Reconstruction of Orbital Floor Defects. Major ARTHUR E. SHERMAN, Springfield, Missouri.

Thursday, 8:00 p.m.

Recent Advances in Ophthalmology

Surgical Applied Anatomy in Eye Surgery. MEYER WIENER, Coronado.

Visual Field Defects Associated with Head Injuries. JOHN S. MCGAVIC, Fort Madison.

The Management of Non-Magnetic Intraocular Foreign Bodies. HARVEY E. THORPE, Pittsburgh.

The Treatment of Strabismus in Children. MAYNARD C. WHEELER, New York.

OTORHINOLARYNGOLOGY

Tuesday, 8:00 p.m.

Treatment of Deafness

The Management of the Chronic Suppurating Ear. JAMES H. MAXWELL, Ann Arbor.

The Fenestration Operation. GEORGE E. SHAMBAUGH, JR., Chicago.

Use of Radium for Conductive Deafness. JOHN E. BORDLEY, Baltimore.

Thursday, 8:00 p.m.

Surgery of the Nasal Accessory Sinuses

Indications for Surgery in the Light of the Use of Antibiotics. HARRY P. SCHENCK, Philadelphia.

Intranasal Surgery. JOHN J. SHEA, Memphis.

External Operations.

PLASTIC SURGERY OF THE HEAD AND NECK

Wednesday 8 p.m.

Cancellous Bone Grafts to the Jaw. TRUMAN G. BLOCKER, Galveston.

Repair of Nasal Defects with Free Composite Grafts of Skin and Cartilage from the Ear. JAMES B. BROWN, St. Louis.

Studies in the Anatomy and the Repair of Cleft Palate.

Preservation of Function Following Resections of Jaw Tumors. LOUIS T. BYARS, St. Louis.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday, 1:30-3:00 p.m.

Rehabilitation of the Surgical Patient and Early Ambulation. Leader, HOWARD RUSK, New York.

Monday, 3:30-5:00 p.m.

The Treatment of Cancer of the Large Bowel. Leader, FREDERICK A. COLLIER, Ann Arbor.

Tuesday, 1:30-3:00 p.m.

Thiouracil in Thyroid Disease. Leader, FRANK LAHEY, Boston.

Tuesday, 3:30-5:00 p.m.

Recent Trends in the Management of Carcinoma of the Cervix. Leader, JOE VINCENT MEIGS, Boston.

Wednesday, 1:30-3:00 p.m.

Anesthesia. Leader, HENRY K. BEECHER, Boston.

Wednesday, 3:30-5:00 p.m.

Protein Metabolism in the Surgical Patient. Leader, ROBERT ELMAN, St. Louis.

Thursday, 3:30-5:00 p.m.

Spinal Cord Injuries. Leader, HOWARD C. NAFFZIGER, San Francisco.

Friday, 1:30-3:00 p.m.

Surgery of the Stomach. Leader, ROSCOE R. GRAHAM, Toronto.

Friday, 3:30-5:00 p.m.

Surgery of the Vascular System. Leader, DANIEL C. ELKIN, Atlanta, Georgia.

SURGICAL SPECIALTIES

Friday, 2:00-5:00 p.m.

Orthopedic Surgery Panel. (Subject to be announced.) Leader, CARL E. BADGLEY, Ann Arbor.

Urology Panel. (Subject to be announced.) Leader, HERMAN L. KRETSCHMER, Chicago.

Plastic Surgery Panel. (Subject to be announced.) Leader, ROBERT H. IVY, Philadelphia.

Neurological Surgery Panel. (Subject to be announced.) Leader, FRANCIS C. GRANT, Philadelphia.

Obstetrics Panel. (Subject to be announced.)

Thoracic Surgery Panel. (Subject to be announced.) Leader, RICHARD H. SWEET, Boston.

OPHTHALMOLOGY

Panel discussions in the field of Ophthalmology are planned for Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock, on the following subjects: Retinal Detachment; Glaucoma; Keratoplasty.

OTORHINOLARYNGOLOGY

Panel discussions on subjects in the field of Otorhinolaryngology are planned for Tuesday, Wednesday and Thursday mornings at 11:00 o'clock on the following subjects, respectively: The Treatment of Ménière's Disease; Osteomyelitis of the Skull; Rehabilitation of the War Deafened.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

AT 2:00 o'clock on Tuesday afternoon there will be held a symposium on Fractures and Other Traumas under the direction of Robert H. Kennedy of New York. This symposium will be devoted to a number of brief presentations by specialists in various fields concerning new or improved methods adopted during the war which are applicable to injury in civilian surgery. The aim is to give a rapid survey of worthwhile gains made during the war which may prove of lasting value in the field of trauma.

Among the fifteen or twenty short papers which are planned are the following:
 Bone Grafts. GEORGE K. CARPENTER, Nashville.
 Spinal Cord Injuries. DAVID H. POER, Atlanta.

Injuries to the Rectum. EDMUND J. CROCE, Worcester.

Transportation of Fractures. WILLIAM J. STEWART, Columbia.

Replacement of Skin Defects. JAMES B. BROWN, St. Louis.

Fractures of the Carpal Scaphoid. MATHER CLEVELAND, New York.

Amputations. RUFUS H. ALDREDGE, New Orleans.

Training of Amputees. HENRY H. KESSLER, Newark.

Rehabilitation. Col. A. WILLIAM REGGIO, Washington.

Compound Fractures Treated with Penicillin and Delayed Primary Closure. OSCAR P. HAMPTON, Jr., St. Louis

SYMPOSIUM ON CANCER

A symposium on cancer is planned for Wednesday afternoon. The Cancer Committee of the College has done outstanding work in furthering the development of cancer clinics in hospitals and providing for the registration of cured cases of malignant disease in the cancer archives. The chairman of this com-

mittee will give a brief review of these activities of the College in opening the symposium.

Other subjects of practical interest are under consideration for inclusion in the program, which is being planned to interest surgeons, pathologists, and radiologists.

COLLECTIVE REVIEW

THE TREATMENT OF HYPERTHYROIDISM WITH THIOURACIL, WITH PARTICULAR REFERENCE TO TOXIC REACTIONS

EDSON F. FOWLER, M.D., M.S., Chicago, Illinois

SEVERAL thousand patients with hyperthyroidism have now been treated with thiouracil, and over a thousand cases have already been reported in the current literature. Hence, it now appears possible to attempt an evaluation of the incidence, types, and severity of the associated toxic reactions. Astwood (2) reported early on the possibility of permanent cures resulting from thiouracil therapy (1). As yet, insufficient time has elapsed since the institution of this treatment to determine how often, and when, permanent cures may be expected. However, it will be of great value to know in what type of patient a permanent cure can be anticipated, particularly since, if a cure is expected, many patients would prefer even prolonged medical management with thiouracil to surgery. It seems obvious that unless the incidence of toxic reactions to thiouracil is low and the incidence of permanent cure is high, thiouracil therapy is therapeutically and economically unsound except in those patients who are poor operative risks following iodine therapy, or who refuse surgical treatment.

TOXICITY OF THIOURACIL

From assembled reports in the literature on the thiouracil treatment of thyrotoxicosis, it is noted that slightly over 13.77 per cent of the 1,573 reported cases have shown some type of toxic reac-

From the Department of Surgery, University of Illinois College of Medicine and the Illinois Research Hospital, Chicago, Illinois.

tion. Of these toxic manifestations, 7 reported cases (an incidence of 0.57 per cent) have proved fatal. Two other fatalities due to thiouracil have been quoted by Vorhaus and Rothendler, but have not been included in this figure; and Curtis has observed another fatality. Of the nonfatal reactions, the majority were so mild or so transitory that it was found unnecessary to discontinue medication, yet in other instances it was only the frequent and close scrutiny of the attending physician which forestalled a fatal termination.

Of all the reactions reported, agranulocytosis, though not a common complication (0.78%), is by far the most important, since it has been responsible for all of the fatalities due to thiouracil which thus far have been reported. A study of these cases reveals that a majority of the patients received an initial dose of at least 1 gm. of thiouracil per day, although in most cases this dosage was later reduced. The reactions may occur at any time during therapy, thus emphasizing the necessity of keeping the patient under close scrutiny at all times. There is no way of predicting what type of patient might sustain reactions, except that the incidence of agranulocytosis is somewhat higher among patients who have had a second course of the drug after its discontinuance for a time.

Agranulocytosis. There appear to be two possible basic explanations for the granulocytopenia or agranulocytosis that is provoked by thiouracil. It might be explained as the result of the depres-

sion of the bone marrow upon a purely *toxic chemical basis* or upon the basis of some *allergic response* to thiouracil. The theory of suppression of the production of granulocytes on a toxic basis is lent support by the studies of Williams, Kay, and Jandorf, who were able to demonstrate that the bone marrow contains the largest proportion of the thiouracil of any body tissue or organ. These workers were also able to demonstrate that the blood cells contain about seven times as much thiouracil as the blood plasma, and that while the erythrocytes, because of their greater number, contained twice the amount present in the leucocytes, the average amount of drug per cell was much greater in the leucocytes. The fact that the majority of cases of agranulocytosis have developed in those individuals on a relatively high dosage of thiouracil, i.e., over 800 mgm. per day, also supports this view. The observation that patients on large doses of thiouracil who develop leucopenia usually recover a normal count when the dosage level is reduced, leads one to a similar conclusion. Some patients have developed agranulocytosis during uninterrupted thiouracil therapy, and this would argue against the probability that sensitization on an allergic basis was the underlying mechanism.

Against the toxic point of view, and in favor of the allergic explanation may be cited the following facts: many cases of serious granulocytopenia have been noted in persons receiving as little as 0.2 gm. of thiouracil per day. Moreover, the majority of granulocytopenic reactions have occurred in patients who have had one or more previous courses of thiouracil therapy and who might thus be said to have been sensitized to the drug. Himsworth believes that a special sensitivity to the drug is present in many persons and that in these cases the failure of ill effects to appear after the first fortnight suggests either that the sensitive subjects are few in number and are eliminated by early detection, or that desensitization is effected by continued treatment (4). The author's analysis of cases reported agrees with Himsworth's conclusion that those persons who exhibit the allergic type of response develop the more serious reactions.

The significance of the development of granulocytopenia (from causes other than thiouracil) can be fully appreciated by quoting Plum:

"The prognosis is extremely bad. Most of the fairly large collection of cases show a mortality amounting to 70 to 90 per cent. In 52 patients, the white cell count was less than 1,000; of these patients, 47 died (90 per cent). In 20 cases, the white cell count was between 1,000 and 2,000; 15 of the patients died (75 per cent). In nine patients, the white cell count was over 2,000 and five of them died (56

per cent). (It might be noted that this was in the days before some of the present day supportive forms of therapy were utilized.) In fatal cases, the disease takes a very rapid course, lasting usually about one week, but often only a few days. The subjective complaints, the overpowering weakness, sore throat, dyspnea and anxiety usually increase during the course of the illness. Though confusion is not uncommon, most of the patients remain lucid till a few hours before death. The conditions grow worse from day to day, the necrotic lesions in the mouth and throat increase and the swelling of the cervical glands gets more pronounced, often associated with coincident edema in the surrounding tissues. The temperature remains at a level of about 104. Most of the fatal cases leave no time for the appearance of complications other than pneumonia."

It should be mentioned that patients with hyperthyroidism *per se* frequently have subnormal leucocyte counts, but from the standpoint of safety during thiouracil therapy, any low counts should be considered a toxic reaction until proved otherwise. Hyperthyroidism presents a characteristic increase in the number of lymphocytes (26), which should not be confused with the relative increase produced by a depression in the production of granulocytes. Neutropenia, when it occurs, appears suddenly in patients whose previous blood counts have been normal both in respect to total white cells and total neutrophils. This observation agrees with that of Bartels and has been true likewise in our series of cases. Himsworth also suggests that the appearance of a leucopenia or neutropenia may be foreshadowed by the appearance of many young neutrophils in the peripheral blood.

Rubinstein reported one case of nonfatal agranulocytosis in a patient suffering from carcinoma of the thyroid with metastases, treated with thiouracil. A very detailed study of the *bone marrow* was made at the time therapy was discontinued and during the period of recovery, which revealed a considerable decrease in the total myeloid count and an arrest of maturation of the myeloid series. In a study of the course of recovery of the bone marrow, after discontinuance of thiouracil therapy, Rubinstein reported that the return to normal of the bone marrow changes precedes that of the peripheral blood. In serial bone marrow aspirations, he found a gradual increase of the number of myeloid cells coincident with a progressive shift to the right. At the same time the peripheral blood counts showed an ascending curve, though lagging behind the recovery of the bone marrow. The cell distribution within the myeloid series of the bone marrow and their total count reached almost normal values about 15 days after the drug was discontinued, although at this time there was still a considerable leucopenia in the peripheral blood (65).

Peripheral blood studies in agranulocytosis due to thiouracil may be summarized as follows: there is no evidence that thiouracil therapy produces a steady depression of the leucocytes in the peripheral blood; rather, neutropenia is a sudden and unexpected occurrence, though possibly the appearance of many young neutrophils in the peripheral blood may give some warning of the possible onset of leucopenia (59). The first warning of agranulocytosis is the reduction of circulating granulocytes below 50 per cent; often the granulocytes may show toxic changes (32); a relative increase of monocytes at the time of the lowest white counts is regarded by many as a favorable prognostic sign (16, 64). Rubinstein's statement that the peripheral blood during recovery lags behind the recovery of the bone marrow, and is characterized by a gradual increase in the numbers of leucocytes, has already been mentioned; Plum, in his monograph on agranulocytosis in general, states that those granulocytes which are present in the fatal cases are most often degenerated, with vacuolated cytoplasm, poorly staining granules and pyknotic nucleus. In the patients who recover or die after hematologic improvement, the granulocytes look quite different, as they are largely young cells that may be designated as premyelocytes, myelocytes, metamyelocytes, and staff nuclears. In most cases, the lymphocytes make up the greater part of the total white cells in the blood of agranulocytic patients. These cells usually look normal but sometimes they show signs of damage, the nuclei being pyknotic and the cytoplasm containing vacuoles. Some significance is to be attributed to the number of plasma cells, as the percentage may be slightly increased (59).

Though the original workers in this field often employed dosages exceeding 1 gm. of thiouracil per day, there is reason to suppose that the use of smaller doses will tend to reduce the incidence of complications (83). Palmer holds that probably 0.6 gm. of thiouracil is the optimum maximum daily dose, though good results have been obtained with an initially high saturation without complications. Palmer has been able to treat with success, in all instances, a group of 50 patients without serious complications, for a period of 1 to 10 months; however, the development of transient leucopenia in 9 cases necessitated the discontinuance of therapy for a period of 72 hours, an effect which disappeared within 48 hours and which did not reappear after treatment with thiouracil had been resumed.

Williams and Clute advocate a similar plan and level of thiouracil dosage, as a means of reducing

the incidence of toxic manifestations, and also because they feel that excessive amounts of thiouracil may increase the size of the goiter as well as accentuate the manifestations of malignant exophthalmos. These workers note also that of 152 cases treated by them, the incidence of reaction was 23 per cent in the first 52 patients to whom large doses of the drug had been given, and only 4 per cent in the last 100 patients who had received relatively small doses.

Granulocytopenia (2, 5, 15, 41) or agranulocytosis (84) may appear at any stage in the course of therapy regardless of the dosage employed, and for this reason it is of paramount importance that frequent white cell counts as well as differential counts be made, care being taken to search for the presence of toxic changes in the cells so that should any tendency toward granulocytopenia exist, it may be noted at the earliest possible moment. If the leucocyte count should drop below 4,000 thiouracil therapy should be discontinued, at least temporarily, even though no toxic changes in the cells are demonstrable; if the count does not return to normal within 48 hours, further therapy is probably dangerous.

In the treatment of agranulocytosis, Goldsmith and his coworkers report that the prophylactic administration of crude liver intramuscularly is of value in prevention of the condition induced by the administration of either sulfonamides or thiourea. Daft and Sebrell, by similar studies, (also on rats) appear to have demonstrated that folic acid is the active agent in liver that is responsible for its protective effect on the granulocytes or their precursors. Pentnucleotide (0.7 to 1.4 gm. daily, intramuscularly) may be given (Williams and Clute).

Vitamin C in 100 mgm. daily doses has been reported by Palmer to decrease the incidence of toxic manifestations. On the basis of their favorable experiences with pentnucleotide, Williams and Clute have advocated the prophylactic administration of brewer's yeast routinely to their patients in the hope of protecting them against agranulocytosis.

Pyridoxine, vitamin B₆, a pyridine compound essential to animal nutrition, has been employed by Cantor and Scott in the treatment of granulocytopenia, with recovery, though here again it is difficult to rule out the possibility of a spontaneous remission.

Once the presence of agranulocytosis has been established several measures have been generally employed to prevent, if possible, the onset of secondary infections which may cause death because of the absence of granulocytes to destroy or

localize the invading organisms before the bone marrow has an opportunity to recover. Whole blood should be administered to provide leucocytes to take over the function of the absent cells in the patient. One should also utilize the bacteriostatic and bacteriocidal effect of penicillin, given in large doses. Penicillin can certainly be given with safety since, according to Kolmer, there have thus far been no fatalities due to the administration of this antibiotic even in cases of agranulocytosis, and hence its use is warranted when indicated. However, should the bone marrow fail to recover its proliferative powers rapidly, even penicillin is powerless to prevent fatal secondary infection.

Sulfonamides have been employed (1) with the purpose of producing bacteriostasis even though many cases of granulocytopenia or agranulocytosis have been recorded as a result of sulfonamide therapy.

Purpura. This complication is rare; only about 6 such cases have been reported to date. In most instances this complication has been associated

with granulocytopenia, a fact which would suggest that it is another manifestation of a toxic depression of the bone marrow which has also adversely affected the megakaryocytes which are supposedly responsible for the adequate production of blood platelets. Joll has reported the development of a case of purpura after 6 months of therapy, which necessitated the discontinuance of medication, though the development of agranulocytopenia was not mentioned. Dunlop has presented a patient whose white blood count dropped to 2,000 (granulocyte count, 33 per cent) while on a dosage of 0.6 gm. of thiouracil per day. Four days after cessation of thiouracil the white cell count had returned to 4,100 and the differential count to normal. Administration of thiouracil was resumed, but a quarter of an hour after the first dose of 0.6 gm. had been given, a violent sensitivity reaction resulted. There was severe headache and pain in the muscles, vomiting, swelling of the lips, face and ankles, a rise of temperature to 101, tachycardia, and a purpuric eruption in the bend of the elbow when the blood

pressure was taken. The reaction took place at 6 p.m., the patient remaining ill during the night and recovering the next day. Recovery was complete in 24 hours. It is interesting to note that the platelet count remained normal during the reaction, whereas the white count fell to 1,880, though returned to 4,100 in 2 days. In view of the absence of a thrombocytopenia in the cases cited, it may be argued that the purpuric manifestations noted should be explained on some other basis than a deficiency in platelets. Flink and Evans have reported one case in which a definite thrombocytopenia was noted.

Dermatitis is the most common evidence of sensitivity to thiouracil; it occurs in about 4.5 per cent of the cases. Dermatitis is meant to include those cases in which either a rash or severe pruritus developed. Dermatitis in itself is of little significance, but the occasional association of this manifestation with other more serious reactions such as chills, fever, and occasional arthralgia and granulocytopenia, warrants careful observation of these patients. For example, Pashkis, et al (58) have reported fever, chills, and joint pain in 2 of 3 patients having a maculopapular rash.

Pruritus. In our series there were 7 instances of pruritus which lasted from 7 to 10 days, though without any other associated toxic manifestation; cessation of therapy was therefore unnecessary. It is probable that pruritus is a skin manifestation of an allergic response to thiouracil. It represents less than 25 per cent of all the toxic skin signs and is perhaps the least significant of all the toxic skin signs, which in turn are the least significant of all reactions.

Urticaria is not so common as dermatitis; it occurs in 0.4 per cent of patients treated with thiouracil (16, 63).

Fever. A febrile reaction is encountered in about 2.6 per cent of patients treated with thiouracil. It does not appear, however, as an isolated manifestation, since it is associated with dermatitis in 50 per cent of the cases, and with granulocytopenia in about 10 per cent of the cases. The patient frequently has a chill with the fever; usually the temperature is about 102 or 103° F., and there is often an associated headache, general malaise, and tachycardia. However, the fever rapidly disappears when thiouracil medication is discontinued. In at least 4 instances fever has been associated with jaundice (26, 36, 58). Rarely, as in Sloan and Shorr's case, jaundice may occur without fever.

The observation of Pashkis and his associates (58) in a patient with a urine urobilinogen of 1:100, a serum bilirubin of 2.5 mgm. per cent, and

a dye retention of 60 per cent, indicates that the liver damage may be the basis of the jaundice. That thiouracil may produce liver damage is further substantiated by Sloan and Shorr, and Gargill and Lesses. However, McGavack and his associates, in a series of 9 patients, were unable to demonstrate evidence of liver damage either by means of hippuric acid excretion, glucose tolerance curves, icteric index, cephalin flocculations, or Van den Bergh reactions. It is, of course, well known that on certain occasions a great deal of liver damage may be present before liver function tests will be positive.

Edema. Edema of the extremities or of the eyelids is a frequent complication of thiouracil therapy, and it occurs in about 16 per cent of cases. There appear to be at least two explanations for this condition. One explanation is that this edema is actually due to myxedema resulting from complete suppression of thyroxine formation by thiouracil. Dunlop and Davidson have also noted the frequent occurrence of edema during treatment, and have been able to show that this edema is unassociated with cardiac failure or signs of renal damage, and that it disappears even though treatment is continued. That myxedema is the explanation for some of these cases of edema is further borne out by the fact that edema is usually not an early complication but rather one which develops after the patient has been on therapy for a month or more.

It is probable that low blood proteins as a cause of edema may be excluded since McGavack, in 9 cases under thiouracil treatment, has observed no constant effect on the blood proteins due to treatment.

A second possible explanation of edema may be in changes in the plasma chloride level or carbon dioxide combining power. Although low blood chlorides have been reported (79), such a finding is by no means constant.

Swelling of the salivary glands. Painful swelling of the salivary glands and lymphadenopathy has been reported in several series as a complication of thiouracil medication. Gargill and Lesses also have reported one case of splenomegaly which they have attributed to thiouracil sensitivity. A majority of these complications have been noted to subside within a few weeks even though therapy is continued. Presumably these reactions are manifestations of a general hypersensitivity to thiouracil, displayed by the reticuloendothelial system. It is likely that the pathological basis for the glandular swelling, as in the case of lymphadenopathy produced by other medication (72), is an acute edema of the glandular or lymphoid

structure, with an associated hyperplasia of the germinal centers in the latter instance, due to thiouracil stimulation.

Arthralgia. Painful joints represent a fairly common complication; the condition occurs in about 0.70 per cent of patients treated with thiouracil. However, it must be borne in mind, as McCulloch and his associates have emphasized, that peri-arthritis is a common complaint in hyperthyroidism. It is not unusual to find arthralgia accompanied by fever and chills, or a rash. The arthritic manifestations mentioned are not unimportant since, as Williams has stated, "except for fever, arthritis and leucopenia, the complications (of thiouracil medication) have been observed to disappear with only a reduction in the size of the dose (78)." However, many of the cases of arthritis do tend to disappear without a reduction in the level of dosage.

Nausea and vomiting. These complaints with an occasional diarrhea have been reported in about 0.84 per cent of patients treated. In Raveno's patients complaining of this complication, symptoms did not develop until the second or third week of therapy. Overdosage may be a cause of nausea and vomiting, but the average daily dose in Raveno's cases was only 0.6 gm. Because of absence of the more severe forms of reaction in association with these gastrointestinal symptoms, it has rarely been found necessary to discontinue medication, although at times a reduction in the dosage level has been made with prompt subsidence of the undesired symptoms.

Miscellaneous complications. To complete the list of untoward symptoms which are rarely encountered, one must add those of hematuria and crystalluria, central nervous system irritation, and anemia. The occurrence of a mild form of pharyngitis (26) and conjunctivitis (37) have also been claimed by some to be a toxic sign though an insignificant one. Palmer, in a series of 50 patients treated with 0.6 gm. of thiouracil daily, observed hematuria and crystalluria in three instances. Palmer has advocated the administration of alkalinizing substances in conjunction with thiouracil, and the adequate administration of fluids. Under this regimen, she was able to continue thiouracil medication which was followed by the disappearance of hematuria and crystalluria.

Recently, Haines and Keating have reported what they believe to be evidence that thiouracil may produce toxic disturbances in the central nervous system. In 2 cases these workers have observed myoclonic contractions of various muscles, particularly the facial muscles, in pa-

tients receiving thiouracil treatment. These contractions were definite and persistent, and did not disappear until several days after thiouracil had been discontinued. That this reaction was actually due to thiouracil is confirmed by the fact that similar evidences of central nervous system irritability reappeared upon two subsequent attempts to readminister the drug. It should be mentioned also that somnolence and mental confusion were evident as a result of the attempt to readminister thiouracil, hence further thiouracil treatment was discontinued. In one instance in our series, a patient complained of numbness and tightness of the fingers for several weeks while under thiouracil therapy, though in the absence of other subjective or objective findings.

REMISSIONS OR CURES

When originally introduced in the treatment of hyperthyroidism, thiouracil was used mainly in the preparation of patients for surgery. However, the success of thiouracil in producing and maintaining a low level of thyroid activity on low maintenance doses, i.e., 100 to 200 mgm. daily, provoked the hope that hyperthyroidism might be abolished by purely medical means (2). Dunlop has stated that the basis for this hope is the fact that long continued hyperplasia may ultimately give way to atrophy of the thyroid gland and that if the patient can be tided over until this occurs, the state of thyrotoxicosis may be cured. Eaton has recorded remissions of 8 months' duration in 4 patients and of 3½ months in an additional 3 patients. Astwood (3) summarized his experience with sustained remissions by noting that when thiouracil therapy was maintained for 6 to 9 months, prolonged remissions resulted; of 11 such patients observed for longer than 3 months, 10 have had no evidence of recurrent hyperthyroidism. All workers have observed that a second course of thiouracil is just as effective as the first when given to patients whose symptoms have recurred after cessation of therapy.

In our experience with patients treated at Illinois Research Hospital, only those patients who are mildly toxic may be expected to obtain prolonged remission following discontinuation of medication, even though the drug has been given over a period of 6 to 9 months. The accompanying table demonstrates that our patients, whose basal metabolic rate was below plus 40 per cent prior to thiouracil therapy, have remained free of symptoms of hyperthyroidism for an appreciable period, whereas those patients whose basal metabolic rate was higher have in all instances suffered a relapse.

TABLE II.—THE RELATIONSHIP OF THYROID TOXICITY TO DURATION OF REMISSION FOLLOWING CESSATION OF THIOURACIL THERAPY (PERSONAL EXPERIENCE)

Case No	Original B M R.	Months Treated	Recurrence	Time (months)
26*	163%	7	Yes	2
22	161%	8	Yes	1
36	155%	5½	Yes	1

9†	141%	5	No	12
23	138%	10	No	5½
24	127%	4	No	7
10†	145%	9	No	7
21	125%	8	No	5
22	135%	8½	No	5
23	124%	3	No	4 plus
39	139%	7	No	4
31	130%	7	No	2 plus
34	134%	6½	No	6
37	130%	6	No	1

*This patient was again placed on thiouracil to which she responded, but subsequently had a relapse within 3 months.

†The basal metabolic rate was a single reading and too high when compared with the patient's clinical condition.

‡This patient had a basal metabolic rate which was not commensurate with her hyperthyroidism, due to the presence of a bilateral pneumothorax for pulmonary tuberculosis.

The reports of the frequency of recurrence without extended thiouracil therapy suggests that only patients presenting mild or moderately severe hyperthyroidism should be treated with thiouracil with the hope of medical cure in mind, whereas patients with more toxic hyperthyroidism should be treated with the idea of performing thyroidectomy as soon as the toxicity is eliminated. Perhaps the administration of thiouracil to the point at which exhaustion of the thyroid occurs (mentioned by Dunlop) would result in more prolonged remissions or cure of patients with even the most toxic cases. However, the end result of such therapy might be the production of a Riedel's struma, which is claimed to be the result of prolonged thyroiditis. Williams (78) has already noted perithyroiditis in glands removed after thiouracil therapy. The extreme hyperplasia of the thyroid produced by thiouracil, the tendency of the thyroid to produce adenomas and carcinoma *in situ* (19), as well as reports that thiourea and allied substances are carcinogenic (6) suggest that neoplasia might be a complication of prolonged thiouracil treatment, but so far no case of carcinoma due to thiouracil has been reported.

It is still too early to state how extensively thiouracil management can be utilized to the exclusion of surgery. Williams and Clute would perform surgery on those patients with very large goiters, those who are unwilling or unable to appear for the necessary frequent check-up examinations, and those who demonstrate undesirable reactions to thiouracil. The high percentage of malignancy in unilateral (solitary) nodular non-toxic goiters, as pointed out by Cole, Slaughter, and Rossiter, may be cited as a possible danger of leaving a thyroid nodule *in situ* permanently, if a permanent remission has been achieved by thiouracil in toxic nodular goiter.

Thiouracil is especially indicated in patients who are so toxic that operation following preparation with iodine is unsafe; likewise the drug is strongly indicated in thyrocardiac patients. Patients who are sensitive or refractory to iodine, as well as those who have concomitant tuberculosis, represent groups in which thiouracil is particularly advantageous. Hyperthyroidism of a low or moderate severity, and recurrent hyperthyroidism following thyroidectomy may constitute indications for medical management with thiouracil to the exclusion of surgery, although additional time for follow up will be required to settle this point.

SUMMARY

In an effort to evaluate the dangers and advantages of the use of thiouracil in hyperthyroidism, a study has been made of 1,573 case reports in the medical literature. The incidence of toxic reactions of all types is 13.77 per cent. The incidence of serious toxic manifestations is not over 4 per cent. The mortality rate in the reports reviewed is 0.57 per cent, although this figure is diminishing somewhat due to the use of less massive doses of thiouracil, and a more complete knowledge of the complications which may result from its use.

Occasionally, a sensitivity to thiouracil appears to have been created when the drug was discontinued and given again after a period of several weeks. However, we have noted no such sensitivity in 8 patients to whom the drug was given a second time.

An estimation of the duration of remissions resulting from thiouracil therapy cannot yet be made, although it would appear that prolonged remissions or cure can be expected only in patients having mild hyperthyroidism.

Surgical therapy seems indicated in severe hyperthyroidism, once it has been adequately controlled by thiouracil, because of the frequent rapid recurrence of symptoms after thiouracil has

been discontinued; surgery is still indicated in patients with large goiters, or goiters causing tracheal compression, as well as in toxic nodular goiters in which there is a question as to their possible malignancy.

Thiouracil will be much superior to iodine in the treatment of thyrocardiac patients. In patients who are sensitive to iodine, or who have tuberculosis, thiouracil will be especially useful. However, in a small percentage of cases, sensitivity to thiouracil will be so serious that iodine must of necessity be the drug for preoperative preparation.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Kirby, D. B.: *Surgical Treatment of Strabismus*.
Am. J. Ophthalm., 1946; 29: 408.

Early surgery for strabismus, especially before the school age of from 4 to 6 years, is indicated. The decision to operate is dependent upon the following conditions: the cycloplegic refraction; the effect of the correction of the ametropia; correspondence; fusion; rotation; monocular and binocular tests in the primary and cardinal direction of gaze; occlusion; correction of amblyopia; excursive exercise; development of normal correspondence; and fusion training.

The surgical operations applicable to the correction of strabismus are as follows:

Tenotomy may be freely applied to the lateral rectus, but only guardedly to the medial rectus; myotomy is suggested for the inferior oblique in some cases of overaction; myectomy for resection of the rectus muscles and for extreme spasms or overaction of the inferior oblique muscle; resection, advancement or tucking for the recti and the inferior oblique muscles; recession or retroplacement for the recti and the oblique muscles.

Recession or retroplacement of a medial rectus muscle should not exceed 5 mm., and of a lateral rectus muscle, 6 to 7 mm.

For esotropia associated with convergence excess, early correction of the hyperopia may prevent the development of strabismus. Recession of one or both medial rectus muscles, or resection or advancement of the lateral rectus is usually necessary in cases of long standing.

For convergent strabismus associated with divergence insufficiency and unilateral or bilateral abduction paresis, resection of the lateral rectus in one or both eyes may be necessary.

For divergent strabismus associated with divergence excess, recession or tenotomy of one or both lateral rectus muscles may be indicated.

For divergent strabismus associated with convergence insufficiency (divergent strabismus greater for near than for distance), convergence exercise, appropriate lenses, and tenotomy or recession of one or both lateral rectus muscles, may be required.

For vertical deviations (hypertropia and hypotropia), tenotomy, recession, resection, or advancement may be used.

For spasm or overaction of the inferior oblique muscle, free myotomy or myectomy at the origin or at the insertion of the muscle may be indicated.

Preoperative study is recommended of the monocular vision, of refraction, accommodation, convergence, divergence, monocular and binocular un-

cover tests in all positions of gaze, degree of fusion, as well as proper diagnosis and orthoptic exercises.

In general, undercorrection is preferred to overcorrection, because the latter is difficult to reconstruct; and the function of an overactive muscle may be diminished by tenotomy, myotomy, myectomy, recession or retroplacement, and the action of a weak muscle may be enhanced by advancement or resection.

Orthoptic training after surgery is urged also as a means of accomplishing binocular single vision with depth perception.
JOSHUA ZUCKERMAN, M.D.

Atkinson, W. S.: *Corneal Section with Long Bevel and Conjunctival Flap for Cataract Extraction*.
Preliminary Report. Arch. Ophthalm., Chic., 1946, 35: 335.

By placing the corneal section in cataract extraction in the avascular corneal tissue and using a long bevel the author aims at the prevention of a leaky wound and postoperative hyphemia. Incision is made with the keratome after a conjunctival flap has been dissected down from a point 4 mm. from the limbus, the keratome being introduced at the side of a previously placed McLean suture and at an angle to produce a long bevel. Withdrawing and partially reinserting the keratome with a sawing motion enlarges the incision, which is completed to one-half the circumference of the cornea with scissors. The amount of the bevel is decreased as the 180 degree meridian is approached. With the pupil well dilated the iris will frequently be concealed behind the corneal ledge; if it is not, from one to three iridotomies are made with the De Wecker scissors (with two sharp points), the iris not being grasped with forceps.

Fig. 1. 1, Usual angle of keratome incision; 2, long bevel obtained when the point of the keratome is directed away from the iris and toward the apex of the cornea.

This operation requires tumbling of the lens because of the forward position of the incision. If the capsule ruptures removal of the lens material is rendered more difficult. If the removal is to be accomplished without tumbling, as in the case of hypermature cataracts, the incision must be less beveled and placed farther back.

Results are tabulated in three series of 100 each; in the first a corneoscleral incision was made with a Graefe knife, in the second a keratome-scissors incision was made, and in the third operation was done by the method described. The number of postoperative leaky wounds was shown to be decreased in the third series, and while hyphemia still occurred, the hemorrhages were smaller and less frequent. The visual results were also slightly better in the third group; in the first series 60 per cent of the patients had a visual acuity of 20/20 or better, in the second series 68 per cent, and in the third group 70 per cent.

WILLIAM A. MANN, M.D.

Laval, J.: Vogt-Koyanagi Syndrome. *Am. J. Ophth.* 1946, 29: 536.

A detailed study of a case of Vogt-Koyanagi syndrome (bilateral uveitis with retinal detachment, poliosis, alopecia, and dysacusia) with several features of interest is presented. The patient was examined so early in the disease that the only abnormal finding was the presence of a few cells in the aqueous, the other findings developing while the patient was under observation. Iridectomies for secondary glaucoma in each eye gave opportunity for histological examination of the iris tissue which appeared extremely necrotic with a moderate amount of round cell infiltration and an occasional plasma cell.

The spinal fluid and aqueous were examined and animal inoculations were performed, all of which yielded no positive results.

WILLIAM A. MANN, M.D.

EAR

Tumarkin, A.: A Contribution to the Theory of the Mechanism of the Auditory Apparatus. *J. Lar. Otol.*, Lond., 1945, 60: 337.

The author states it is now commonly thought that the ear is critically damped. He points out that such a system is not compatible with great selectivity. As a result, many authors have abandoned Helmholtz's resonance theory for the hydrodynamic theory of Rebaul, which is based on the propagation of a disturbance in a fluid column with elastic walls.

He reviews the evidence for critical damping and shows that the cochlear microphonic behaves differently from the nerve action potential. The former can follow a phase shift while the latter cannot. The subjective effect of phase shift is momentary silence. The decay period of a sound necessary to produce the sensation of immediate cessation is constant, regardless of the intensity. It is believed that the microphonic and the action potentials arise from two different structures—one is critically damped (probably

Reissner's membrane) while the other is resonant (probably the basilar membrane).

The author admits the necessity for great but not critical damping in the end organ in order to account for the analysis of complex sounds. He tries to reconcile great damping with high selectivity, and points out that frictional damping may be replaced by damping by reverse radiation in the ear. The round window dissipation of energy into the middle ear may be the damping mechanism, and this is large because of the overall good impedance matching that facilitates the absorption of sound energy from the air into the cochlear fluid.

The tension of the middle ear structures and their minute displacements indicate that frictional damping which is proportional to velocity is at a minimum here. The middle ear should be considered as a pressure-driven rather than a velocity-driven system. In such a system obliquity of the drum is no disadvantage and, indeed, by allowing a greater drum area, it has been found to be advantageous to sensitivity.

The inner ear on the other hand is considered to be velocity driven with the pressure gradient, started at the oval window, suddenly falling when it reaches the appropriately resonant basilar fiber. This fiber is undergoing maximum velocity and displacement, which is compatible with the findings in masking experiments. There are mass movements of finite columns of fluid with low impedance because of small frictional resistance.

If the middle ear is pressure driven, then the function of the intratympanic muscles is to hold the middle ear tense and insure close mechanical coupling of the ossicles. A primary listening function for these muscles is proposed, and, with greater sound intensity, some protection against overexcursion, although it is pointed out that even at 120 DB this is only .01 millimeter at the drum.

If damping in the cochlea occurs as a result of reverse radiation then frictional losses in the cochlea may be minimal. The action potential has been shown to be due to the half cycle produced by outward movement of the stapes. The author suggests that functional damping may occur only on the other half of the cycle (inward movement of the stapes). He suggests that the cochlea itself may, by shunting effects, protect itself against large stimuli. He then considers the function of the basilar membrane transversely, and points out the difference in sensitivity of the inner and outer hair cells. This may be used to explain recruitment and variations in pitch with intensity. The low impedance of the cochlea makes it possible for sound energy in air to directly activate the cochlea. The author states that this is clinically true and is dependent on a freely moveable stapes.

About a 10 DB threshold loss may be expected from a central perforation, about 25 DB from loss of the middle ear apparatus, and about 60 DB loss if an extensive fibrosis of the stapes is also present.

JOHN R. LINDSAY, M.D.

Lierle, D. M., and Reger, S. N.: Correlations between Bone and Air Conduction Acuity Measurements over a Wide Frequency In Different Types of Hearing Impairment. *Laryngoscope*, 1946, 56: 187.

The authors believe that as long as significant differences of opinion exist with regard to the efficacy of different test methods and the interpretation of results, further work along these lines seems pardonable, if not necessary. In their study, the attempt is made to present a description of the instruments, techniques, experimental controls, and results, that will not add to the general confusion but will be instrumental in clarifying certain test procedures, objectives, and interpretations of the functional examination of hearing.

The following aspects of bone conduction acuity measurements are discussed:

1. Difficulties involved in tuning fork measurements.
2. The "air-conduction bone-conduction differential" of audiometer vibrators.
3. Results of audiometric measurements.
4. Masking of bone conducted sound.
5. The Weber, Schwabach, and Rinne tests with the bone conduction vibrator.
6. The Gelle, Bing, and occlusion tests with the vibrator.
7. Increased bone conduction acuity.
8. Disproportionately decreased bone conduction acuity.
9. Threshold of vibration by bone conduction.
10. Reliability of audiometer bone conduction vibrators.
11. Interpretation of the relationships between air and bone conduction acuity threshold measurements.

Because of the obvious difficulties involved in obtaining accurate quantitative bone conduction measurements with forks, attention next was directed to a study of certain physical characteristics of a new type of electrically activated bone conduction receiver or vibrator which was designed for use with the audiometer. This particular vibrator is constructed so that its energy output is practically free from variations due to the amount of pressure with which it is held against the skull.

The results of bone conduction measurements obtained with the vibrator used in this study in no way contradicted or disagreed with the findings from measurements with forks. The vibrator demonstrated superior or desirable characteristics in the following respects:

The vibrator makes possible the testing of bone conduction acuity in terms of measurements which enable direct immediate comparison between the air and bone conduction acuity.

The vibrator permits the testing of bone conduction acuity (Schwabach) over wider frequency and greater intensity ranges than is possible with forks.

Air and bone conduction acuity determinations obtained in the same measurement terms give the

information sought in the Rinne test over wider frequency and intensity levels than are possible with the forks.

The Weber test can be performed over wider frequency and intensity levels than can be accomplished with the forks.

The Gelle, Bing, and occlusion tests can be conducted with a higher degree of accuracy with the vibrator than is possible with forks.

Increased bone conduction is a real phenomenon, but is of such rare occurrence that it may be considered the exception rather than the rule in cases of middle ear impairment.

Increased bone conduction is of most frequent occurrence for frequencies below 1,500 cycles.

A given patient may exhibit both increased and decreased bone conduction in the same ear simultaneously—increased for low, and decreased for high frequencies.

It is more difficult to achieve effective masking for bone conduction than for air conduction measurements.

Properly constructed, calibrated, and used bone conduction vibrators possess sufficient reliability and accuracy to justify their use.

The development of such a vibrator for general use will constitute a progressive advancement in the functional examination of hearing.

JOHN F. DELPH, M.D.

Lempert, J.: Tympanosympathectomy; A Surgical Technique for the Relief of Tinnitus Aurium. *Arch. Otolaryng.*, Chic., 1946, 43: 199.

During the past twelve years the author has been conducting a study of the problems of tinnitus in relation to disease of the middle and inner ear. Many observations were made on both the suppurative and the nonsuppurative type of otitis media.

The most striking observation was the extreme rarity of tinnitus in patients suffering from long standing suppurative lesions with polyp and cholesteatoma involving the tympanum proper. This fact suggested, among other things, that tinnitus may be the result of inflammation of some anatomic structure which is normally present within the tympanic cavity.

In a series of 100 patients complaining of tinnitus, upon whom the fenestration operation for otosclerosis was being performed, there was frequently observed an abnormal congestion of the mucoperiosteum covering the cochlear promontory.

In another series of 60 patients who were operated upon for chronic otorrhea, the normally present tympanic plexus with its branches was found to be absent.

On the basis of his observations, the author believes that many cases of tinnitus aurium may be a tonus impulse transmitted from the middle ear by the tympanic plexus to the inner ear.

The author has devised an operation for the relief of tinnitus aurium, without damage of the hearing acuity of the patient. The operation has been per-

formed on 15 patients, 10 of whom were freed of their tinnitus.

JOHN F. DFLER, M.D.

Syvertson, J. T., Hless, W. R., Krafchuk, J., Josselyn, E. H., and Others: Otitis Externa; Clinical Observations and Microbiological Flora. *Arch. Otolaryng.*, Chic., 1946, 43: 213.

Otitis externa is a clinical entity with a high morbidity in military personnel on tropical duty. The microbiological flora of the external auditory canal in otitis externa, which in most cases is mixed, differs from the flora of the normal auditory canal in the same clime by the inclusion of one or more pathogens. The causative agent of otitis externa can be any one of a variety of bacteria and fungi. Among these are *Pseudomonas aeruginosa*, *Klebsiella ozaenae*, *Staphylococcus aureus hemolyticus*, *Aspergillus*, and probably *Monilia tropicalis*, *Actinomyces*, and *Proteus*. The role of fungi in otitis externa has undoubtedly been overemphasized, whether as primary or secondary agents of infection.

As the response to treatment in otitis externa is determined by the causative agent present, exudate from each ear should be cultured before treatment is started. The efficacy of each of the medicinal preparations and antibiotic drugs recommended for treatment of otitis externa should be tested by employing groups of 20 cases in which the etiological factors are known.

NOAH D. FABRICANT, M.D.

Eagle, W. W.: Secretory Otitis Media. *Ann. Otol. Rhinol.*, 1946, 55: 55.

The newer method of incising the ear drum and aspirating the fluid in patients with secretory otitis media (formerly known as catarrhal otitis media) has, in the author's hands, shown excellent results. The author states that complications are practically nil. Of 172 patients so treated only 1 developed purulent otitis media following myringotomy and aspiration of the nonpurulent fluid.

The author offers no definite causative factor which would account for the increased frequency of the disease, although it is known that blockage of the eustachian tube is the primary cause of secretory otitis media. It is possible that the entity may be virus-induced, since the disease is almost epidemic in form. Although secretory otitis media is more prevalent during the colder months of the year, it is not necessarily associated with upper respiratory infections.

NOAH D. FABRICANT, M.D.

Johnston, C. M.: The Treatment of Chronic Otitis Media. *J. Lar. Otol.*, Lond., 1945, 60: 303.

The author maintains that the successful treatment of chronic suppuration of the middle ear depends on a correct appreciation of its cause. Infected granulation tissue is often the sole cause of chronic suppuration, and its removal will frequently cure the otorrhea. In many instances the cause of the condition is in the nose, the paranasal sinuses, or in the pharynx, and if it is discovered early, irreparable damage may be prevented.

Infection of the sinuses is a common cause of chronicity of otitis media. Poor general health, exposure to the elements, and bad housing conditions undoubtedly aid other factors in keeping the infection active, which explains in part the frequency with which such diseases tend to relapse under conditions of active military service, and the good results obtained by hospitalization of patients.

In the conservative treatment of a suppurating ear, it is most important that pus and debris be removed from the meatus at frequent intervals. Polyps and granulation tissue should be removed at the earliest opportunity. These opinions are based on the experience of the author at the Horton Emergency Hospital.

NOAH D. FABRICANT, M.D.

Banham, T. M.: The Treatment of Chronic Otitis Media. *J. Lar. Otol.*, Lond., 1945, 60: 307.

The author reports a series of 200 cases of chronic otitis media and describes the results obtained with the conservative method of treatment used at one Royal Air Force clinic. The cases are grouped according to their otoscopic appearance.

In conclusion, the author states that the satisfactory end result of conservative treatment is not unlike the successful result of operative treatment. He believes that with operative treatment, deafness is much more likely to be increased, whereas with conservative treatment, hearing is often improved. However, if, in the event of a recurrence, the ear is likely to be neglected and further treatment is not obtained, some form of radical mastoidectomy is probably a safer procedure.

NOAH D. FABRICANT, M.D.

Lodge, W. O.: Operative Treatment of Chronic Otitis Media. *J. Lar. Otol.*, Lond., 1945, 60: 315.

The author believes that since chronic otitis media implies degeneration, successful operative treatment cannot be assured, and that treatment of the disease remains a tantalizing problem. Nevertheless, in his hands the proportion of good results has been sufficiently high to atone for occasional disappointments, and it is believed that operation may be of value if it can be discerned from successes and failures how the disease can be prevented.

In 78 of 100 patients, healing has been complete. The successful results do not include cases in which only the mastoid cavity proper was healed, but do include cases in which the cavities remained dry, provided keratoses were not neglected.

Operations by the endaural route allow observation of living pathology and correlation with x-ray appearances of pneumatization, thus harmonizing treatment with surgical principles and affording research into the prevention of chronic otitis media.

The newer antiseptics affect the after treatment of this condition.

The transmeatal approach is described, and measures to enlarge the lumen of the meatus and avoid perichondritis are discussed.

NOAH D. FABRICANT, M.D.

Thornell, W. C., and Williams, H. L.: Apical Petrositis; Medical and Surgical Management in Cases with and without Complicating Meningitis. *Arch. Otolar.*, Chic., 1946, 43: 393.

Three cases of apical petrositis are presented because they illustrate the solution of the problems presented in the medical treatment and surgical management that the otologist may encounter in cases of petrositis with or without complicating meningitis. These cases stress the importance of a careful and complete history. They demonstrate the need for adequate and primary surgical treatment in instances in which symptoms of petrous involvement develop in the presence of an apparently adequately draining ear, and they discourage dependence on chemotherapy alone. They show the necessity for approaching each case as an individual problem. The selection of the surgical approach is not planned prior to operation but is determined at the time of operation according to the anatomicopathological changes present.

Prior to operation on the petrous pyramid, the preparation should be such as to place the patient in the best possible physical condition. It is advisable that the treatment of complicating meningitis should be well under way, preferably with a combination of sulfonamide compound and penicillin. The sulfonamide which we have found to be clinically superior at the present time is sulfadiazine. When used alone in cases of meningitis, it is advisable to maintain a blood level of 18 to 20 mgm. per 100 c.c.; this has been found to be adequate. In cases of petrositis without complicating meningitis, when using sulfadiazine alone, blood levels of 10 to 12 mgm. per 100 c.c. are advisable. When using large doses of sulfadiazine it is very important that adequate fluid intake and output be maintained. The intake should be 3,000 cubic centimeters per day, and urinary output 1,500 cubic centimeters or more. Even though the fluid intake may be adequate, renal complications may occur if the dose of sulfadiazine is high. This may be prevented by adequate alkalization.

The combination of a sulfonamide and penicillin produces a synergistic effect. In cases of meningitis, penicillin should be administered intrathecally as well as intravenously (or intramuscularly) because of the fact that penicillin does not pass freely to the spinal fluid from the blood stream. After the meningitis has been brought under control it is necessary to eradicate the disease in the petrous pyramid surgically because, unless this is done, the infected focus may lie dormant, protected by a layer of necrotic material and pus, and then will become reactivated after the withdrawal of chemotherapy and penicillin. Apical petrositis with its high incidence of intracranial complications is not a condition in which it is safe to temporize, although such a course may be followed with occasional success in cases of uncomplicated mastoiditis if the patient is under careful observation.

When possible, drainage of suppurative foci in the petrous pyramid should be accomplished by follow-

ing preformed cell tracts to the involved region. When a cellular pyramid is present, increased room in and around the region of the labyrinthine capsule is usually present. If adequate drainage can be secured by following the perilyabyrinthine cell tracts, well described by Ramadier, the necessity of destroying the hearing can be avoided. Therefore the authors believe that drainage of apical petrositis should be done in stages, the perilyabyrinthine regions being first explored and the more destructive procedure of complete apicectomy being reserved for a later date if it is subsequently found necessary. If closed apicitis is present, in which preformed tracts cannot be found on careful and extensive exploration of the perilyabyrinthine regions, complete apicectomy by the Ramadier-Lempert technique is indicated without further delay. If history and examination definitely indicate a suppurative region in the pyramid medial to the capsule of the labyrinth, adequate drainage must be secured.

The performance of complete mastoidectomy alone, followed by a period of observation, is a policy that should be pursued only when there is a reasonable doubt that the symptoms represent apicitis. As has been pointed out by one of the authors (Williams), disease sealed off in the cells along the sigmoidal angle is capable of producing a Gradenigo syndrome, and such infected cells may have been overlooked. This should rarely happen, however, if an adequate exploration of the mastoid cells has been done. If meningitis is present and no adequate explanation for its presence is presented during the course of complete mastoidectomy, the dura should be uncovered both over the temporosphenoidal lobe and over the sinus and cerebellum. If still no explanation of intracranial extension of the disease is found, apicectomy should be seriously considered, because of the frequency with which apicitis has been found to be the underlying cause of such extension. The association of chronic sphenoiditis with apicitis, as pointed out by Eagleton, should be borne in mind.

NOSE AND SINUSES

Wright, R. W., and Boyd, H. M. E.: Aerohematoma of the Sinuses. *Arch. Otolar.*, Chic., 1946, 43: 357.

Aerohematoma is suggested to designate a hematoma which may occur in the mucosa of a paranasal sinus after failure of the sinus ostium to admit air during sudden descent from a high altitude.

Twelve such cases are reported, in 9 of which the frontal sinus was involved; in 2 cases, and possibly 3, both the frontal sinus and the antrum were involved, and in 3 the antrum alone was involved.

The outstanding symptom is rapid onset of severe pain either over the frontal region or, in the case of the antrum, over the side of the face and teeth. The sharp pain soon subsides, leaving soreness which lasts for several days. The location of the pain is indicative of the sinus involved.

Eight of the twelve patients had a slight cold or sinusitis at the time of flight; the others had no ob-

vicious predisposing pathological condition. The amount of pressure necessary to pull the mucosal layers apart, and to rupture small vessels and form a hematoma, is slight. Descents from around 5,000 feet may produce the lesion. The hematoma may develop slowly and not be demonstrable on x-ray at once, but later a well defined shadow appears and in a day or two the entire sinus may become cloudy. Resorption requires from 3 to 10 weeks. There may or may not be free hemorrhage from the sinus.

The treatment consists of nasal shrinkage, and surgical intervention is rarely necessary.

JOHN R. LINDSAY, M.D.

MOUTH

Stenstrom, K. W., and Waldron, C. W.: Transitional Cell Carcinoma. *J. Oral Surg.*, 1946, 4: 175.

The authors report a case of extensive transitional cell carcinoma without glandular metastases, occurring in the upper jaw of a woman aged 48. Treatment with deep x-ray therapy by which a tumor dose of 1,200 tissue roentgens were delivered, resulted in a disappearance of the tumor with no recurrence after a period of 12 years. The term "transitional cell carcinoma," they believe, should be retained since this tumor is especially radiosensitive. They consider it to be the same as a lymphoepithelioma.

JOHN R. LINDSAY, M.D.

NECK

Bechgaard, P.: Tendency to Hemorrhage in Thyrotoxicosis. *Acta. med. scand.*, 1946, 124: 79.

Observations over a period of many years have indicated a disturbance of the coagulation of the blood in thyrotoxicosis. A toxic hepatitis leads one to expect a decrease in coagulation of the blood because of a reduction of prothrombin.

The present study comprises the results obtained in the treatment of 50 patients with thyrotoxicosis (45 women and 5 men). Forty-one of the patients were operated upon during the period of this investigation. Routine and special blood studies were carried out on the patients. The author found no relation between an increase in metabolism and the clotting time of the blood, or the prothrombin content of the blood. The fibrinogen was not lowered, but in several cases it was increased. In a few of the patients the bleeding time was increased. The clotting time for patients with thyrotoxicosis is prolonged. In all cases the antithrombin content of the blood was within normal limits. Transitory urobilinuria was observed in 9 cases. There appeared to be no relation between the decrease in the prothrombin content of the blood and its coagulability. In 8 cases the bleeding time was increased. The antithrombin and fibrinogen content of the blood, the thrombocyte count, and the clot retraction were found to be normal.

RICHARD J. BENNETT, JR., M.D.

Lederer, J.: Particular Aspects of Osseous Growth and Calcium Metabolism in a Case of Exophthalmic Goiter in a Child of 6 Years (Aspects particuliers de la croissance osseuse et du métabolisme calcique dans un cas de goître exophtalmique chez un enfant de six ans). *Ann. endocr.*, Par., 1946, 7: 34.

In the case here reported the child (a girl of 6 years) had had a normal birth and development until 4 years of age when she underwent a tonsillectomy and soon afterward began to grow rapidly in height. Also about this time the parents noted that the thyroid gland had begun to enlarge and the child became very nervous, was extremely restless, always complained of being "hot," sweated copiously, and developed a voracious appetite.

Examination disclosed a tall, thin child with mild exophthalmos, a slight sign of Graefe's disease, and a pronounced tremor. During the period of medical treatment and preparation for surgery the patient exhibited an abnormal rate of growth in height, and her dentition and ossification was that of a child several years older; yet there was widespread evidence of osteoporosis and a highly unfavorable (negative) calcium balance.

After removal of the orange-sized, firm, diffusely hyperplastic goiter by means of a subtotal thyroidectomy the rate of skeletal growth returned to normal and the calcium balance showed a positive balance, which is normal for this period of childhood.

JOHN W. BRENNAN, M.D.

Swann, C. G.: Deep Infections of the Neck with Particular Reference to the Role of Dental Foci. *Ann. Otol. Rhinol.*, 1946, 55: 29.

Dental diseases of the lower jaw are a most frequent source of deep infections involving the fascial planes of the neck; yet it is remarkable that relatively few complications follow the numerous dental procedures carried out in a constantly infected field. Careful and frequent observation following dental procedures of the lower jaw is of the utmost importance.

The hyoid bone and mylohyoid diaphragm serve to divide the neck into an upper and a lower compartment. The mylohyoid muscle is hung like a broad hammock from the mylohyoid ridge of the mandible to the hyoid bone and fuses superficially with the deep cervical fascia. Division into potential spaces results from deep projections of the superficial layer of the deep fascia. Each space is so limited by dense fascia and muscle attachments that much pressure must be exerted before infection extends into adjacent areas. It must be kept in mind that these anatomical subdivisions apply to potential spaces only; that is, areas containing connective tissue and occasional glands. A cavity develops only after infection creeps in and suppuration takes place.

The streptococcus is the predominant organism, with the spirochete of Vincent nearly always present. There is marked edema, and the intracellular spaces

are filled with a serous, somewhat hemorrhagic exudate.

Painful swelling in the suprahyoid region of the neck following any dental procedure, trauma of the lower jaw, or in the presence of dental disease is the first sign of deep infection. The area involved is brawny or boardlike, and tender; only rarely is fluctuation present, and then, late in the disease. The swelling usually spreads rapidly, but the course may be mild for several days and then suddenly assume an alarming character. In the beginning there is no redness of the overlying skin, but edema is present and there is no pitting on pressure. Infection of the parotid space is often rapidly followed by involvement of the lateral pharyngeal space.

When an abscess is located definitely in the submental space, a midline incision in the submental triangle, extending from the symphysis to the hyoid bone, is made. The relief of tension and the establishment of drainage are usually all that is necessary to provide prompt and rapid recovery. Occasionally an abscess will point just beneath the mucosa of the floor of the mouth, between the tongue and the medial surface of the alveolus. Free incision and gentle exploration are indicated.

For a submaxillary abscess, the incision should begin just anterior to the angle of the jaw and pass forward parallel to and about 1 centimeter below the mandible for three-fourths of the distance to the midline anteriorly. It will divide the skin, platysma, cervical fascia, mylohyoid muscle and the anterior belly of the digastric muscle. The only large vessels encountered are the facial artery and vein as they pass up the posterior lateral side of the submaxillary gland; these are isolated, ligated, and cut.

Supportive disease of the parotid calls for massive drainage of the gland. This is obtained best by an incision which starts above, near the zygoma, immediately in front of the ear, extending downward to a point beneath and well in from the angle of the jaw. The skin and subcutaneous tissue are then reflected forward, which permits a wide exposure of the entire gland. Incision may be made to a considerable depth within the gland without danger of injury to the facial nerve, as these fibers lie rather deep. For abscess in the pterygomaxillary space, an incision is made along the superior border of the zygoma, and the fibers of the temporal muscle are dissected to expose the infratemporal fossa. A grooved director or small hemostat is directed downward and inward under the zygomatic arch for a distance of from 1 to 1½ inches, and entry made into the pterygomaxillary space.

When the lateral pharyngeal space is involved secondarily after operative treatment on the submaxillary and sublingual areas, the original incision is carried directly backward and slightly upward following the curve of the mandible, to the anterior border of the sternomastoid muscle. Many surgeons prefer the T-shaped incision of Mosher, particularly when the principal area of involvement is in the lateral pharyngeal space. After division of the super-

ficial tissues and cervical fascia, Barnhill selects his entrance on a line from the middle of the submaxillary gland to the middle of the parotid. A dull dissector is inserted and passed inward and upward in the direction of the tonsillar fossa, and an index finger in the pharynx, placed just anterior to the tonsil, will detect the end of the approaching instrument. When the posterior compartment of this space has become involved it may be necessary to investigate the carotid sheath, or its contents. When the carotid sheath presents even slight pathological changes, it should be opened and its contents inspected. Particular attention is given to the internal jugular following previous intermittent chills and a septic type of temperature. If the vein is thrombosed, the limits of the clot are determined and the vessel is ligated above and below the involved area. If the thrombus in the internal jugular is below the entrance of the facial vein, this should be ligated and the diseased portion of the internal jugular excised and removed.

A tracheotomy is done when there is marked difficulty of respiration. The type of anesthetic employed in the various operations described is important. Local anesthesia is satisfactory in mild uncomplicated cases requiring simple incision and drainage. Intravenous anesthetics have been used with good success. Inhalation anesthetics may be used if the airway is free. Nitrous oxide is not recommended, however, because of the high incidence of spastic respiratory obstruction. EARL O. LATIMER, M.D.

Lederer, F. L., and Howard, J. C.: Wartime Laryngeal Injuries. *Arch. Otolaryng.*, Chic., 1946, 43: 331.

This series of 43 cases includes some of the most representative types of laryngeal injury. The reports of 8 cases of indirect injury to the larynx have been abstracted, and the authors present 1 case of thermal trauma to the larynx and 2 cases of indirect trauma to the larynx.

The immediate treatment is always directed toward maintaining the patency of the airway; external injury may cause edema and subsequent suffocation. During the lifesaving measure of inserting a tube into the larynx or trachea, sedatives should be used sparingly. Vessels should be ligated carefully, and the wound should not be sutured too tightly because of the danger of emphysema. The authors believe that direct laryngoscopy is of great importance (before treatment is instituted) as a means of determining the amount of pathology in the larynx.

The most frequent complication of laryngeal injury is perichondritis. In cases in which the perichondrium has been injured, many complications may result. The occurrence of tracheo-esophageal fistulas is common; stenosis and web formation frequently follow laryngeal injury.

Débridement within the larynx is contraindicated. In the present series of cases, the more conservative type of surgical procedure was followed with excellent results. Stenosis of the upper part of the larynx may be treated by the use of core molds. Following

laryngeotomy, an esophageal voice must be developed.

RICHARD J. BENNETT, JR., M.D.

Cutler, M.: Cancer of the Larynx; 5 Year Results of Concentration Radiotherapy. *Arch. Otolar.*, Chic., 1946, 43: 315.

One hundred eighteen consecutive cases of carcinoma of the larynx, which were treated by irradiation from April, 1938 through December, 1942, are reported. In this series 42 per cent 5 year cures and 39 per cent 3 year cures were obtained.

When the cords are freely movable or only partly fixed by carcinoma, the curability is high. However, when the cords are completely fixed, cure is less common and laryngeotomy is indicated.

This study shows that a group of patients with intrinsic squamous carcinoma of the larynx too advanced for laryngofissure and requiring total laryngectomy have been cured by irradiation. Laryngectomy should be limited to intrinsic lesions with complete fixation of the cords in good surgical subjects with a good life expectancy.

RICHARD J. BENNETT, JR., M.D.

Dargent, M., and Papillon, J.: Motor Disturbances following Excision of Lymph Glands of the Neck. How May We Avoid Them? (Les séquelles motrices de l'excision ganglionnaire du cou. Comment les éviter?) *Lyon chir.*, 1945, 40: 718.

Prophylactic excision of the lymph glands in the course of treatment of oral cancer may produce a

paralysis of the lower branch of the facial nerve and certain muscles of the shoulder, especially the upper portion of the trapezoid muscle.

It is essential in the dissection of the cervical lymph glands to preserve the facial nerve. It is highly desirable to preserve the cervicospinal anastomosis and the trapezoid branches of the cervical plexus, which prevent dropping of the scapula and permit normal elevation of the arm. It is possible to remove completely the upper and lower groups of lymph glands located underneath the trapezoid muscle and yet to preserve the most important nerves.

The authors dissected 30 anatomic specimens to study the location of the facial nerve and 12 specimens to investigate the location of the spinal nerve and the cervical plexus. The best way to preserve these nerves is to dissect the glands from above downward and from the anterior toward the posterior region. The technique is described in some detail.

Integrity of the muscles in the involved regions was established in 18 of 20 patients from 6 to 9 months after employment of the method advocated by the authors.

Failure in one of the cases was ascribed not to the surgical procedure but to a necrosis of the bones of the lower jaw following radiotherapy. No failure was recorded in 11 cases in which preservation of the spinal nerve had been attempted.

JOSEPH K. NARAY, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Falconer, M. A.: Surgical Problems in the Later Stages of Penetrating Head Injuries. *Austral. N. Zealand J. Surg.*, 1945, 15: 75.

This article was given as a lecture before the New Zealand branch of the Australasian College of Surgeons. It has to do with the surgical problems in the later stages of penetrating head injuries.

The author points out that the chief risks of indriven foreign bodies are epilepsy and abscess formation. Few retained foreign bodies, whether metallic or bony, are likely to cause these complications unless they are actually lodged in the cortex or are al-

ready infected. If an adequate operation has been performed shortly after infliction of the wound, such foreign bodies will have been removed. Metallic fragments from projectiles are sterilized by the heat of the explosion, and those that penetrate deeply into the white matter usually remain silent. Therefore, deeply situated metallic bodies are best let alone unless they become implicated in a brain abscess. Once the original wound is healed, it is folly to attempt to remove a foreign body at a secondary operation, unless it is causing epilepsy or seems likely to do so. If this principle is not followed many patients will be worse off after than before operation.

It is pointed out that following the first World War post-traumatic epilepsy occurred more fre-

Fig. 1. Operative findings in Case 1. Top inset shows siting of scalp and bone flaps in relation to the skull defect. Left, The appearance after reflection of the bone flap; the metallic fragment has partially penetrated the dura. Right, The appearance after reflection of the dura; the foreign body has invaginated the brain immediately behind the excitable motor cortex, which has been mapped out by a thyatron stimulator. The bottom inset shows an intact cortical vessel coursing beneath the foreign bodies, as revealed during their removal.

A. Twitching, left side of mouth. B. Twitching, left eyelids. C. Twitching, left arm. D. Twitching, left arm. E. Silent. F. Stiffening of left arm, muffled voice.

quently in pensioners in whom foreign metallic bodies had been removed at a secondary operation, than in those in whom the foreign bodies had been left undisturbed. The instance was 53 per cent in the first group as opposed to 38 per cent in the second group. The reason for this disparity between these two groups is undoubtedly the additional trauma, which was so frequently inflicted upon the brain by ill-judged attempts at removal. These statistics, however, should not deter one from recommending operation in properly selected cases, for it is well known that in the right type of case benefit can frequently be conferred by careful removal of a foreign body.

The author then gives 4 case studies, the first of which is an example of a superficially situated foreign body which caused the symptoms and was removed at an early stage. Case 2 is an example of a superficially situated foreign body causing symptoms, which was removed at a later stage. Case 3 is an example of a deeply situated metallic foreign body, the removal of which was not contraindicated. Case 4 is another example of a deeply situated metallic fragment, the removal of which was not indicated. It is pointed out that foreign bodies, unless actually lodged in the cortex, do not of themselves cause epilepsy, and need not be disturbed unless they are associated with an inflammatory lesion. The paramount importance of an adequate trial of medical treatment before excision of a brain scar is stressed.

The author then gives his method of repairing skull defects by the use of split-rib grafts.

The treatment of recurrent and delayed cerebral abscesses is discussed and a series of cases is described. Many pneumoencephalograms and other roentgenograms are given.

Finally, the author discusses the excision of brain scars which are causing post-traumatic epilepsy. The frequency with which epileptic attacks occur after penetrating skull wound has been estimated from as low as 9.8 per cent to as high as 45 per cent. In the selection of patients for operation, there are two principles to be considered. The first concerns the time of the onset of attacks, the author expressing the opinion that excision of the brain cicatrix should not be contemplated until more than 2 years have elapsed since the wound was inflicted. The second, which is the more important, is that no patient should be submitted to operation unless a few-quate treatment with phenobarbital and other anticonvulsant drugs has been tried and has failed. It is important that the scars should be widely excised. For this reason the author operates through a bone flap rather than through a trepanation.

PAUL MERRITT, M.D.

Carmody, J. T. B.: The Repair of Cranial Defects with Special Reference to the Use of Cancellous Bone. *Am. J. Surg.* 71: 301-305.

Tarantula has been used very successfully in the repair of large and extensive cranial defects. On certain occasions, however, it appears to act as a

foreign body and may have to be removed. The author had 2 such cases. In place of tarantula, he recommends the use of cancellous bone in small to medium sized defects.

Following the making of the flap incision, the aponeurosis is dissected to the edge of the bone defect, and the scar, which may begin at the margin of the defect, is carefully dissected from the dura. It is most important not to pierce through the scalp area to its external surface. All bleeding points must be meticulously controlled, and it is believed this best accomplished with fibrin foam packs. Freshening up the bone edges around the defect should be done to preclude the opening of diploic vessels. Cancellous chips averaging 1 centimeter in diameter are planed into mosaic layers, entirely filling the defect. Chips of this size are readily obtained by lifting them off the graft with the rongeur. As a final step, the pericranium surrounding the exposed bone defect is freed and turned back over the borders, partially covering the cancellous chips. The scalp flap is sutured with a light compression dressing is applied.

The method of taking the graft is as follows: The crest of the ileum is exposed and the fat surface of the bone laid bare. The outer cortical layer is cut with a rotary bone saw and turned down. The strips of the medulla are sliced free, and when a sufficient amount has been obtained the cortical layer is replaced and sutured into its former position.

With the foregoing technique the author has had excellent success in the repair of small and medium-sized defects. He recommends the use of tarantula in defects of the orbital ridge and frontal region, though cancellous bone has been used in these positions.

JAMES W. FERGUSON, M.D.

Wright, R. D.: Concussion and Contusion. *Ann. Surg.* 1945, 19: 631.

The author discusses the mechanism of concussion and contusion with regard to the forces applied to the head. The possible results of applying forces free, stationary head are:

1. Linear acceleration of the whole skull and its contents in the line of the applied force.

2. Angular acceleration of the whole skull and its contents about an axis within or without the skull's bony frames.

3. Distortion of the skull, with the possibility of the resulting bone structure of the skull sustaining transverse waves which are highly damped by the liquid loading of the contents and surrounded by the meninges.

4. Distortion of the skull, with the possibility of a general change in pressure within it.

The author has conducted experiments with cats to further determine the effects of these forces on the cranial contents. It was concluded that the effects of concussion and contusion is that of distortion of the elements of the neuraxis. The most extensive displacement of any part of the brain is the displacement away from the neck. It may occur in the cortex and contents when the head is rotated (H. Brown) and may result from distortion of the cranial contents.

may also result from the liberation of bubbles of the intracranial blood in areas of reduced pressure.

HOWARD A. BROWN, M.D.

Reichert, F. L.: The Surgical Treatment of Vascular Anomalies of the Premotor Area Producing Epilepsy. *Surgery*, 1946, 19: 703.

The author reports a series of 15 cases in which vascular anomalies of the premotor area were encountered as the cause of epileptic attacks. These attacks were of jacksonian character, and a presumptive diagnosis of "vascular anomaly" was made as a result of the history, neurological examination, and pneumographic studies.

In 9 of the patients, premotor signs were present.

Various types of vascular anomalies were encountered, including cortical angiomata or hemangiomas, dural angiomata, and callosal angiomata. The patients were treated by surgical exploration and coagulation of the abnormal vessels. This procedure frequently produced a transient hemiplegia until normal collateral vascular channels developed.

Subtemporal decompression was employed in some instances, as well as intravenous hypertonic solution and ventricular puncture, to effect a smoother postoperative course.

Two of the 15 patients had only temporary relief from the procedure, 7 were benefited with milder and less frequent attacks, and 6 (40%) were completely relieved following surgery.

HOWARD A. BROWN, M.D.

Schuller, A., and Morgan, F.: Cephalohematoma Deformans. *Surgery*, 1946, 19: 651.

Although most cases of infantile cephalohematoma are completely absorbed and leave no residue, it is known that calcification and bizarre osteoblastic and osteolytic changes may occur. These are rare, however, and this presentation of 5 cases studied many years after the onset give valuable roentgenologic data of this condition. The ages of the patients were 72, 71, 54, and 27 years.

The lack of surgical or postmortem examination, however, leaves some doubt in regard to the actual pathological state of the tissue and hence complete verification remains in some doubt. However, biopsy in 1 case revealed a pressure necrosis of the bone, primarily traumatic in origin, with induced hemorrhage and rarefying osteitis.

In 4 of the cases a definite history of trauma, occurring either in infancy or childhood, was present, while in the remaining case the swelling was noted since childhood. There was no evidence of neurological disturbance, and despite rather severe deformity it was believed that surgery would not be required.

The pathological picture is that of newly formed bone with osteoporosis and osteosclerosis forming sequestra and cysts. The new bone originally forms along the elevated pericranium, the dura mater, and, finally, within the swelling. Fresh hemorrhages may occur and partially destroy the swelling, even many

years after the trauma. Usually the paranasal sinuses are not developed on the ipsilateral side.

Roentgenologically there is a peculiar circumscribed hyperostosis involving the calvaria and base of the anterior part of the skull. The eccentric conformation with cystic cavities, osteoporotic and osteosclerotic areas suggestive of Paget's disease, and eburnated hyperostosis in the base all combine to make the picture fairly characteristic.

JACK I. WOOLF, M.D.

Tschiasny, K.: The Site of the Facial Nerve Lesion in Cases of Ramsay Hunt's Syndrome. *Ann. Otol. Rhinol.*, 1946, 55: 152.

Ramsay Hunt's syndrome designates the occurrence of herpes zoster at the cephalic extremity, particularly at the auricle and usually associated with neural signs of the seventh and eighth cranial nerves. Hunt explained the syndrome in the following way: inflammation of the geniculate ganglion produces herpes in the "geniculate area," that is, the part of the auricle receiving its sensory supply from the seventh cranial nerve. This inflammation causes sufficient pressure on the motor fibers of the seventh nerve to cause paralysis. On the other hand, herpes of the face or of the occipitocollar region was thought to be due to inflammatory lesions of the gasserian ganglion or of the first and second cervical ganglia, respectively, and the associated facial paralysis was believed to be produced by inflammation of the geniculate ganglion which was not of sufficient magnitude to cause herpes of the geniculate area but yet sufficient to cause facial palsy.

This concept has not been universally supported. At autopsy in a case of occipitocollar herpes associated with facial palsy Denny-Brown, Adams, and Fitzgerald found destructive lesions of the second cervical ganglion, inflammatory in nature, and patchy infiltration in the course of the facial nerve, but no changes at all in the geniculate ganglion.

The author makes a careful analysis of the seventh cranial nerve. He divides it into four parts for the purpose of better localizing the section of the nerve which is affected in various types of cases.

1. Infrachordal—all of the nerve distal to the branching of the chorda tympani. In lesions of this part of the nerve, there is motor paralysis of the face, the posterior auricular muscle alone escaping if the lesion is extracranial, but if the lesion is in the intracranial portion of the nerve, this muscle is involved also. Further, if the lesion is extracranial, sensation at the geniculate zone of the auricle is not disturbed, but if it is intracranial there are disturbances of sensation in this area. The sense of taste, and movements of the palate are normal. There is hyperlacrimation and epiphora. There are no signs of stapedius involvement.

2. Suprachordal—the part of the nerve between the chorda tympani and the geniculate ganglion. The signs are as before, with the exception that there is also a loss of taste in the anterior two-thirds of the tongue and a slight diminution of salivation if the

lesion is below the branch of the nerve to the stapedius muscle. If proximal to the latter, there is phonophobia, a term suggested by the author as more appropriate than hyperesthesia acoustica or others which have been used.

3. Transgeniculate—the area occupied by the geniculate ganglion including the branching of the greater superficial petrosal nerve. The signs are as before except that hyperlacrimation is replaced by hypolacrimation or even the absence of lacrimation on the affected side. The uvula and soft palate deviate to the good side.

4. Suprageniculate—the part of the nerve above the branching of the greater superficial petrosal nerve. The signs are as in the preceding divisions, but *without* loss of taste in the anterior two-thirds of the tongue as the taste fibers passing off in the greater superficial petrosal nerve escape the lesion. This fact has been noted by several other authors.

Two cases of herpes with facial palsy are then presented and analyzed with respect to the location of the lesion in terms of the given subdivisions.

When the entire syndrome is thus examined, it seems evident that it cannot be well explained by

Hunt's theory. However, the cases presented here and others culled from the literature fall into the author's classification very well.

Since both patients recovered, the classification could not be subjected to the final test of pathological examination.

The author would restrict the use of the term "Ramsay Hunt's syndrome" to those cases in which the geniculate ganglion actually is involved, that is, the herpes oticus syndrome. The cases of herpes facialis and herpes of the occipitocollar region, he feels, should be classified separately.

ROBERT E. GREEN, M.D.

Fincher, E. F.: Craniotomy and Total Dissection as a Method in the Treatment of Abscess of the Brain. *Ann. Surg.*, 1946, 123: 789.

In the mass of somewhat confusing literature on the treatment of brain abscess, with the wide divergency of opinions regarding the proper management of such lesions, this article stands out with distinction because of its clarity and instructiveness. The author has used his 5 illustrative case histories with strong effect to demonstrate various lesions and the

Fig. 1.—A. When the cortex has been exposed the depth of the abscess is determined by the exploratory ventricular needle.

B. The overlying cortex may be transected or a circumcisional uncapping performed to give an adequate exposure of the dome of the abscess. The exposed cortex and medullary brain are protected with cottonoid strips soaked in penicillin. The abscess is punctured under electrocoagulation.

C. Syringe aspiration of the cavity for gaining space for capsule dissection and for specimen collection minimizes wound contamination as compared with open suction methods.

D. The total amount of penicillin solution injected is far less than the volume of pus aspirated. The needle is withdrawn under electrocoagulation.

Fig. 1.—E. The small opening made by the aspirating needle is closed with the cupped forceps and, if possible, this traction-hold is maintained throughout the capsular dissection.

F. The friability of the abscess wall or the size of the lesion may necessitate piecemeal dissection. This is accomplished best with cotton pledget dissection, the abscess wall being folded into its own cavity.

G. Gelatin sponge strips soaked in thrombin and then penicillin are placed in the medullary cavity. They are useful in sealing an opening into the ventricular cavity should such an accident occur in the dissection.

H. The dura is sutured tightly as in routine craniotomy following removal of a tumor. (Courtesy of J. B. Lippincott Co.)

ingenuity with which he has met various problems. Fincher recognizes the great advantage in being able to dissect out a firmly encapsulated abscess *in toto*, much like a tumor mass, as do many other surgeons, but he points out that when this is not possible he has carried out radical total dissection of the entire mass and of any suspicious contiguous tissue, aided by heavy but well controlled doses of sulfa drugs and penicillin, with a surprisingly low postoperative morbidity and as yet no mortality. It may be necessary, as a temporizing procedure, first to tap the abscess to relieve any severe and increasing intracranial tension, especially if time for removal of the causative focus must be taken. He makes the point, too, that the primary focus (osteomyelitic bone, a petrosal abscess, a mastoid infection) must be removed before or at the time of definitive attack on the intracranial abscess, else no cure of the abscess may be expected. Following a preliminary tapping of an abscess he has used thorium dioxide to outline the extent of the abscess cavity, and in at least 1 case this procedure led to the discovery of an unsuspected multilobular abscess which was later completely and successfully removed.

Figure 1 illustrates quite well most of the technical steps in his treatment of brain abscess. Ventriculography is frequently used for accurate localization of the lesion. A craniotomy or osteoplastic flap is then performed, the dura mater opened, the wound packed with penicillin-soaked cotton strips, the depth of the abscess estimated by the ventricular needle, a minimal cortical excision made, and then, with the coagulating electric current, the exposed

capsule is prepared for aspiration. Through the one needle the pus is aspirated and the penicillin solution is injected, following which the somewhat collapsed capsule is gently teased out of place with soft cotton pledgets. The closure is the same as that for any clean craniotomy, with tight closure of the dura mater, galea, and skin, without drainage. Penicillin or sulfa drugs may be left in the intracranial portion of the wound.

JOHN MARSH, M.D.

SPINAL CORD AND ITS COVERINGS

White, J. C., and Peterson, T. H.: Lumbar Herniations of Intervertebral Discs; Value of Surgical Removal for Naval Personnel. *Occup. Med.*, 1946, 1: 145.

In a series of 947 civilian cases of herniated intervertebral disc treated by operation, by various workers, about 63 per cent of the patients were rendered completely or nearly free of symptoms, and they were able to do their former work; 17 per cent were able to carry on in a more limited capacity, and 15 per cent were not benefited.

Since 1940, few articles dealing with the results on service personnel were written, and most of these did not include long follow-ups. However, in both the United States and the British military services, the trend has been toward conservative treatment because it was observed that operations were not successful in getting a large percentage of men back to full duty.

In the present series, 39 cases which were operated upon for the removal of a herniated disc are pre-

sented. All of the patients had severe low back pain and sciatica which failed to respond to a month's trial of conservative orthopedic therapy. All but 2 of this group showed a definite filling defect on the pantopaque spinogram; 101 patients with syndromes suggesting lumbar disc herniation were examined by myelography. In the absence of a clear cut projection or root filling defect, 56 were returned to the orthopedic service for conservative treatment. The 2 patients upon whom an exploratory operation was performed after normal spinograms were obtained, had symptoms and signs of root compression, and an elevated spinal fluid protein. In both cases definite disc herniation was found.

In the group subjected to operation, it was obvious that if the pain was not relieved, all would have to be discharged from the service.

Twenty-four men had follow-ups to the end of 1944 (from 5 months to 2½ years after operation). Of this group, 13 (54.2 per cent) had excellent results, these were service men on active duty or veterans on unlimited activity. Five patients (20.8 per cent) had good results, these were service men on limited duty, but ready for full duty, or veterans engaged in moderately active work. Five patients (20.8 per cent) had uncertain results, these were still on limited duty, and presented recurrent back ache or sciatica. In 1 patient the result was a failure, and the patient was discharged from the service on account of weakness in his back.

In the remaining 15 cases, only the disposition at the time of discharge from the hospital was known. Three (20.0 per cent) were returned to active duty, 10 (66.7 per cent) were returned to light duty or transferred to a convalescent hospital with a good chance of return to full duty; and 2 (13.3 per cent) were transferred to a convalescent hospital with a poor chance of return to duty.

Four of the group had multiple ruptures of the intervertebral discs. At least 3 of these had excellent operative results.

Three patients had recurrent pain due to rupture of another disc and 4 others had later disability after an initially successful result. One of the latter was noted to have loose articular facets at the time of operation.

In addition, exploratory operations were performed on 7 other cases, but the diagnosis of herniated disc was not substantiated at that time.

In general, it is believed that spinal fusion should not be done unless structural defects in the vertebral column are obvious. When spinal fusion is done, a much longer period of hospitalization is required, which always results in a loss of desire to return to active service.

It is most important for doctors and nurses to impress upon these patients that they have not had a serious operation, because it is easy for this group of patients to magnify postoperative complaints, and thus become eligible for pension.

It must be emphasized that in service hospitals, surgical removal of protrusions of intervertebral

discs should be performed only in clear cut cases, and on patients who are otherwise in sound physical condition and eager to return to their military duties.

ROBERT E. GREEN, M.D.

Friberg, S., and Iltsh, C.: On Late Results of Operative Treatment for Intervertebral Disc Prolapses in the Lumbar Region. *Acta chirurg. scand.*, 1946, 93: 161.

The authors report the results of check-up examinations done 5 years after the surgical removal of prolapsed lumbar intervertebral discs in a series of 44 patients. Forty-two of these patients were working; 32 had returned to their former profession which was physical labor in 22 cases. The average convalescence before they returned to work was 20 weeks. After 5 years, 83.8 per cent of the patients were free from sciatic pain and 70 per cent were free from low back pain; 65 per cent showed normal mobility of the lumbar region. The Achilles reflex was still absent in every patient, and more than half of them still had areas of hypalgesia. In none of the cases did the authors, who are orthopedic surgeons at the University of Stockholm, perform a fusion, and they do not recommend a combined operation. However, a fusion may be considered at a later date if the low back pain has not subsided.

All of the patients were first treated conservatively and all had preoperative myelographic studies. The authors do not consider a case of longstanding lumbago or sciatic pain with an unstable low back as being fully investigated without myelography, and they make a definite differentiation between a prolapsed intervertebral disc and degeneration of the disc without prolapse.

GEORGE PERRET, M.D.

Livingston, W. K., and Newman, H. W.: Spinal Cord "Concussion" in War Wounds. *Ann. Surg.*, 1946, 54: 131.

In a study of 821 cases of major nerve injury resulting from bullets or shell fragments, the authors noted a transient quadriplegia in 33, or 4 per cent of the cases. There was no evidence of direct damage to the central nervous system in any of the cases. The transient nature of the disturbance suggests that it is comparable to concussion of the cerebrum; hence the cases are presented as spinal cord concussion.

Several case reports are presented. The usual features were a retention of consciousness, a sudden complete loss of voluntary control and of sensory perception of the extremities, and a rapid return of normal function of the extremities not directly injured.

Several postulations as to the causative factors are discussed. The possibility of a massive afferent impulse bombardment of the spinal centers is presented. However, the occurrence of a transient quadriplegia without major nerve involvement, and its absence in many patients with nerve injury at a distance from the spinal axis, suggests that this hypothesis cannot be accepted. The authors believe

that a dyssynchronization of neural activity results from the massive stimulation by the trauma. Whether the trauma is to the spinal cord, its meninges, or nerves is not known. JACK I. WOOLF, M.D.

Ilagelstam, L.: On the Deformities of the Spine in Multiple Neurofibromatosis (von Recklinghausen). *Arch. chir. scand.*, 1946, 93: 169.

After a general review of the literature on multiple neurofibromatosis and the skeletal changes associated with it, the author analyzed a series of 105 cases of deformities of the spinal column collected from the literature. The most common of them were kyphoscoliosis, scoliosis, and kyphosis with occasional gibbus formation in the thoracic and dorsolumbar regions. To these, the author added a case in which he found a marked dorsolumbar kyphoscoliosis with an hourglass shaped deformity of the first, second, and third lumbar vertebrae. He thought this deformity to be the result of a trophoneurotic growth disturbance secondary to the neurofibromatosis. GEORGE PERRET, M.D.

PERIPHERAL NERVES

Björkstén, G. af: Position of the Fingers and Function Deficiency in Ulnar Paralysis. *Acta. chir. scand.*, 1946, 93: 99.

The author analyzed the anomalies in the position of the fingers in 152 cases of ulnar nerve lesions treated at the Finnish Red Cross Hospital in 1944 and 1945. The lesion was above the elbow in 87 cases and below the elbow in 65 cases and produced various degrees of clawing of the fingers. He found no clawing in 7 per cent, clawing of the fifth finger alone in 10 per cent, of the fourth and fifth fingers in 41 per cent, of the third, fourth, and fifth fingers in 18 per cent and of the second, third, fourth, and fifth fingers in 24 per cent of the cases.

He deduced that the lumbrical muscles responsible for the deformities were innervated by the ulnar nerve and showed considerable variations in their innervation. He reported poor functional results of the small hand muscles after ulnar nerve suture and ascribed them to a degeneration of the muscles partly caused by the hyperextension of the paralyzed lumbricals. A splint of the clasp type applied across the hand over the metacarpophalangeal joints enabled the patients to extend their fingers, relieved the clawing, and increased the functional results.

GEORGE PERRET, M.D.

SYMPATHETIC NERVES

FitzGerald, P. A.: Sympathectomy for Hypertension. *Irish J. M. Sc.*, 1946, ser. 6, 109.

From a general review of the literature, the author concludes that essential hypertension accounts for 90 per cent of all cases of elevated blood pressure. A summary of 21 personally observed cases is presented. It is believed, from the work of Goldblatt (on renal ischemia), Page and others (on renin), and

Homer Smith (on renal blood flow) that man has both a neurogenic and a hormonal control over renal blood flow. "... one must conclude that essential hypertension is nervous in origin, and only involves the kidney at a comparatively late stage." Such a judgment directs sympathectomy as a treatment for this condition. Factors produced by sympathectomy which are important in the reduction of hypertension are increased renal blood flow, stabilization of the reflex vasomotor mechanisms in peripheral vessels, and reduction in the amount of adrenalin which enters the circulation.

Patients for whom a sympathectomy is considered must have essential hypertension and not hyperpiesia secondary to endocrine disorders, nephritis, or aortic coarctation. The kidneys and the heart should be well compensated and the most favorable age group is below 40 years. Of value in assessing the status of the individual and indicating the prognosis after operation are ophthalmoscopic examination of the retinal vessels, renal function tests, and pressure changes during sedation. Eye signs are not reliable guides for individual prognosis although people with slight arteriolar constriction and/or minimal vessel crossing changes give better operative results. Reduction of renal function below a Conway figure of 50 carries a bad prognosis, but in the absence of renal necrosis or nitrogen retention, kidney function is considered irrelevant. When the diastolic pressure is more than 140 operation is useless as a means of pressure reduction, but many symptoms are ameliorated. The prognosis seems worst in a combination of high pulse and high diastolic pressure. Best results are with a pulse pressure which is less than half of the diastolic. When a fall in blood pressure to normal occurs after sodium amytal sedation, a sympathectomy is likely to help considerably.

Other tests used are the cold pressor test of Hines and Brown, the variation in pressure from bed rest to exercise, and the change from hyperventilation to apnea. The more labile the blood pressure, the better the expectation following operation. Even when these tests do not indicate a good operative result, occasionally sympathectomy causes an unusually good response. This is true more frequently in the acute than in the chronic cases of hypertension. Often subjective symptoms such as headache, palpitations, and dizziness are significantly improved following operation so that blood pressure levels cannot be the sole criteria of success or failure.

Many variations of operations have been described to denervate the kidney, adrenal region, and to promote peripheral vascular relaxation, viz.

1940 Lumbodorsal sympathectomy. Smithwick

The surgical treatment of hypertension grew slowly in the minds of European workers and achieved final practical significance by surgeons in the United States. The operation most commonly utilized at present is that proposed by Smithwick. The author suggests the following revisions of Smithwick's classic procedure as described in 1940. The patient is placed in a lateral position and tilted 45° toward the operator. This avoids the cardiovascular strain imposed by the prone position and visualizes well the sympathetic chain. Instead of dissecting all the nerve trunks downward, he advises pulling the sympathetic nerves forward and working up the chain, but dissects down the splanchnic nerves. This is in accordance with the anatomical relation of the sympathetic nerves and intercostal vessels.

The side effects of the lumbodorsal sympathectomy are trivial for the most part. In the order of decreasing frequency they are: vascular hyperemia of the lower limbs which become permanently warm and dry. Rarely the hands become cold as though they were the site of sympathetic hypertonus. Postural hypotension frequently occurs, but soon disappears within 2 to 3 months. Bandaging the legs or wearing an abdominal binder alleviates this somewhat. Some believe that bilateral section of the first lumbar ganglion interferes with ejaculation, but not potency, in the male. In the female the pain of menstruation and of the first stage of labor disappears. Increased intestinal peristalsis may occur especially in elderly people. This is easily controlled by atropine and disappears spontaneously in a few weeks.

The author has performed 16 sympathectomies of the lumbodorsal type in 9 patients, removing the sympathetic chain from the ninth dorsal to the second lumbar, as well as the splanchnic nerves. He waits 2 weeks before doing the second stage. He obtained 2 excellent, 4 very satisfactory results, and 1 poor result in a period as long as 2½ years. (The

other patients are awaiting the second stage of the operation). He has had no operative mortality. In 8 other instances he considered patients unsuitable for operation. Of these, 6 died within 4 months after this conclusion. He believes sympathectomy is the best method in use at present for the treatment of essential hypertension.

MISCELLANEOUS

Florini, E.: Bilateral Cervical Ribs Which Became Manifest after Trauma of the Hands (Costa cervicale bilaterale resa manifesta da un trauma alle mani). *Arch. Ital. chir.*, 1944, 66: 180.

A 22 year old patient developed an indolent ulcer on the dorsum of the right hand following a burn with nitric acid. The roentgenographic examination revealed a bilateral hypertrophy of the transverse processes of the seventh cervical vertebra.

A partial resection of the right transverse process of the seventh cervical vertebra, combined with a section of the corresponding scalenus muscle and subclavian sympathectomy caused the disappearance of the syndrome of pallor, perspiration, dystrophy of the nails, and tactile and thermic hypersensitivity.

Eight months later the patient developed a similar condition on the left hand following an injury. A similar procedure was employed as on the right side and in addition to it a fibrous band uniting the cervical rib with the first thoracic rib was severed. The patient recovered. A trauma of the hands may activate a latent syndrome of a cervical rib. This observation is important from the medicolegal point of view.

A fibrous band uniting the cervical with the first thoracic rib deserves attention as it may be responsible for a great part of the symptoms. If the connective tissue is found to be edematous or in a stage of proliferation, its removal should supplement the anterior scalenotomy and the perisubclavian sympathectomy.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Leucutia, T.: The Value of Orchidectomy in the Treatment of Carcinoma of the Male Breast. *Radiology*, 1946, 46: 441.

If the estrogenic origin of mammary carcinoma in the human being is accepted, it is reasonable to expect that some of the observations made in animal experiments should hold for both men and women.

In mammary carcinoma of the female, surgical or roentgen castration has been applied periodically for nearly half a century, and the conclusions as to its value are still far from definite.

From the literature it may be seen that:

1. In the presence of osseous metastases, roentgen castration is beneficial in one-third of the cases of mammary carcinoma, producing symptomatic relief and perhaps some prolongation of life.

2. In local recurrences and generalized visceral metastases, roentgen castration is of no particular value, although sporadic favorable results are described in the literature.

3. In the operable group of mammary carcinomas, routine roentgen castration is considered a futile effort, having no influence on the final results. More recently, considerable benefit is being claimed from surgical castration (bilateral oophorectomy) in the premenopausal stage, but the number of cases published is still too small to warrant final conclusions.

In mammary carcinoma of the male, castration, which is best accomplished by bilateral orchidectomy, has been done, but it is not surprising that the conclusions as to its value should be indefinite.

Leucutia presents 2 cases of carcinoma of the male breast, in which, at a very advanced stage, orchidectomy was performed as a therapeutic measure. In the first case radical mastectomy and repeated series of deep roentgen therapy led to a satisfactory result for 9 years, when general osseous metastases developed. Within a few weeks following a bilateral orchidectomy there was a spectacular improvement, and the metastases completely disappeared in a period of 2 months. At the present time, nearly 2 years later, the patient is in good condition and apparently free of carcinoma.

In the second case a radical mastectomy followed by four series of deep roentgen therapy failed to prevent the development of local recurrence, which assumed the character of cancer en cuirasse. There were also signs of beginning metastases in the liver, but there was no invasion of the osseous system. Two years later, a bilateral orchidectomy was done. There was a very remarkable improvement, with a 20 lb. weight gain within a few months after the operation. However, 6 months after the operation, extensive local recurrence developed as well as widespread visceral metastases and the patient expired 2 months later.

The reason why osseous metastases from mammary carcinoma of both sexes respond more readily than local recurrences or visceral metastases to the castration treatment, particularly in appropriate association with other methods of therapy, is not clear. It is possible that a neoplasm which, despite everything, produces local recurrence or swiftly invades distant viscera, represents a cancer of extremely great activity from the beginning and the removal of the estrogen source would have little or no influence on it. On the other hand, metastases to the osseous system are known to occur at a somewhat later period, which suggests a slower rate of growth of the cancer. Moreover, the osseous system itself does not possess a function as vital for the survival of the body as, for example, the liver, brain, and most other viscera, a fact which, in the end, results in an apparently additional prolongation of life.

STEPHEN A. ZIFMAN, M.D.

TRACHEA, LUNGS, AND PLEURA

Maurer, E., and Blades, B.: Hernia of the Lung. *J. Thorac. Surg.*, 1946, 15: 77.

True hernia of the lung is a protrusion of the pleural covered lung beyond its normal boundaries, through an abnormal opening in the thoracic enclosure.

According to location, lung hernias may be classified into three groups:

1. *Cervical.* These usually occur through the superior aperture of the thorax, in the interval between the sternocleidomastoid and scalenus anticus muscles, following some deficiency in Sibson's fascia, and are usually congenital.

2. *Thoracic.* These are most common because trauma is so common in this region. Herniation usually occurs anteriorly because the congenitally weak area, near the sternum, is covered only by the pectoral muscles, which do not give the support given by the trapezius, latissimus dorsi, and rhomboid muscles posteriorly.

3. *Diaphragmatic.* The extreme rarity of diaphragmatic hernia is probably due to the imbalance between the positive intra-abdominal and the negative intrathoracic pressures so that, in injuries of the diaphragm, the abdominal viscera usually are displaced into the corresponding hemithorax, while the lung collapses.

According to etiology, lung hernias may be classified into two groups:

1. *Congenital.* These occur most commonly in the superior thoracic aperture, or anteriorly in the inter-spaces near the sternum.

2. *Acquired.* These are traumatic, spontaneous (as a result of local weakness in the boundaries of the thoracic cavity, with an abnormal increase in intrathoracic pressure), or pathologic (after abscesses of

the chest wall, empyema necessitatis, tumors, and tuberculous caries of the ribs).

As a rule, pulmonary hernias present few symptoms, especially if nontraumatic. The first complaint is tenderness over a new swelling in the chest, which increases in size on forced expiration. In the acute traumatic or postoperative varieties, however, the picture is obscured by severe symptoms secondary to injury of the chest wall or pleura. The presence of a palpable orifice in the thorax, through which a smooth, soft, crepitant, reducible mass appears on forced expiration, makes the diagnosis evident. Should the mass appear on inspiration and disappear on expiration, prolapse of the abdominal viscera into the thorax should be suspected.

In differential diagnosis, the following conditions should be considered: subcutaneous emphysema, empyema necessitatis, lung suppuration and degenerating malignancy breaking through the chest wall, tumor of the thoracic wall, tuberculous caries of a rib, and gas bacillus infection of the thorax or chest wall with crepitation.

The treatment is essentially surgical. Any defect of the chest wall can usually be repaired by plastic procedures involving only structures which are part of the chest wall—rib, periosteum, and muscle. The most important feature in the repair of pulmonary hernias is the covering of the defect with sturdy bone, or with periosteum which will produce bone. The most satisfactory repair of average size defects is obtained by the suturing of periosteal flaps developed from ribs immediately above and below the margins of the hernial orifice. The freeing of adhesions and of the lung about the margins of the hernial orifice, combined with the creation of a local pneumothorax, is important in producing a cushion between the lung and the freshly repaired chest wall. Endotracheal administration of the anesthetic agent is necessary, since this insures safety when the pleura is opened widely, and makes it possible to leave the lung in the desired degree of inflation.

SAMUEL KAHN, M.D.

Nylander, P. E. A., and Kivikanervo, K.: On Extrapleural Pneumolysis in Pulmonary Tuberculosis. *Acta chir. scand.*, 1946, 93: 325.

Investigations of extrapleural pneumolysis are too often based on limited materials and short observations. This is a continuous series of 118 cases of pneumolysis in 115 patients observed between 1939 and 1944; 47 were men and 68 women, the youngest being 13 years old and the oldest 50. The authors' opinion regarding the nature of the cases in which pneumolysis should be applied, which is based on the successful results as well as the failures at the sanatorium Kiljavanummen Parantola, is reported.

At the end of the observation period 91 patients survived, 67 without bacilli. Twenty-four patients had positive sputum and most of these were unable to work. The earliest death took place 3 months after the operation. Treatment was often given in cases in which no other collapse therapy was possi-

ble. Bilateral collapse treatment offers excellent selectivity.

Productive forms of disease in which the general condition has been improved as much as possible are most suitable. In approximately every third case of the exudative type, tuberculous infection arises in the extrapleural space, and from 10 to 15 per cent of these cases develop specific empyema cavities which often heal at the cost of collapse; yet this hazard is less than that of disseminations and pneumonias occurring in thoracoplasty with exudative disease.

In old cases the tissue overlying the cavity may derive some of its blood supply through the endothoracic fascia. Separation of the parietal pleura may interfere with the blood supply with rupture of the cavity by necrosis. When the patient is known to have had a serious pleural affection, pneumolysis must be considered contraindicated. The difficulties in establishing a collapse increase the further down the cavity is located, but because the thorax remains practically intact, pneumolysis may be used when the function of the circulatory system is no longer quite normal in individuals of more advanced age. Results have been better in women than in men.

Under local anesthesia with the patient in the sitting posture an oblique incision is made at the apex of the shoulder blade at the second or third thoracic vertebra. A length from 6 to 8 cm. is removed subperiosteally from the fourth or fifth rib. Strict asepsis and meticulous hemostasis are important.

The lung is left unstripped some distance above the hilus in order that the cavity may be compressed against the mediastinum and will not drop to the floor of the space where there is no fixed base.

The first group of complications includes large postoperative hemorrhages, nonspecific infections, and the formation of exudate. The second group comprises specific infections and perforations of the lung. Collapse created by means of pneumolysis has been completed either by thoracoplasty or by phrenic excision in 12.2 per cent of the author's cases on account of obliteration of the space. An additional pneumolysis is indicated when coagulation makes obliteration evident. It should be done about a fortnight after the first operation when clot is still removable and specific infections have not yet arisen to develop into severe extrapleural empyemas.

In cases in which a sterile exudate persists pneumothorax must promptly be converted into oleothorax. For empyemas the authors use gomenol-parafin oil alone or with azochloramid rinses. For the most dangerous complication, bronchial fistula, there is no reliable remedy.

Four weeks are allowed for drying up and healing of the space for converting pneumothorax to oleothorax. Initial air refills with slightly negative pressure are generally followed by oil. In a few pneumothorax cases the lung re-expanded normally, as it may also do with oil. In most of the cases oil has remained for years in the extrapleural space without deleterious effect.

LYNN JOHNSON, M.D.

Santy, P., Bérard, M., and Fraisse, P.: Surgical Treatment of Abscess of the Middle Lobe of the Right Lung (*Le traitement chirurgical des abcès du lobe moyen du poumon droit*). *Lyon chir.*, 1945, 40: 179.

Among 620 lung abscesses the authors encountered 6 located in the middle lobe on the right side. Such location creates 2 problems—diagnosis and surgical approach.

As judged from published observations, signs of an abscess in the middle lobe are not dramatic. Purulent expectoration, sometimes fetid, is not abundant and elevations of the temperature are not very marked. Hemoptysis, frequently recorded in the evolution of such abscesses, may lead to a diagnostic error, suggesting a neoplasm or tuberculosis rather than an abscess. The ventilation of the lobe depends entirely on 2 axial bronchi and may be suppressed easily by suppurative processes. Such functional obliteration of the bronchi renders the evacuation of the abscess difficult. Vomiting is rare and the roentgenograms seldom visualize fluid and air because evacuation of the cavity is difficult. The inflammatory reaction and congestion of the bronchial mucosa are responsible for the relative frequency of slight hemoptysis. The obliteration of the bronchi causes atelectasis, which is frequently visible in roentgenograms. However, the interpretation of the films is not always easy, especially if they are taken only in the anteroposterior direction, but the opaque triangle visible in pictures taken in the lateral direction is quite characteristic. Tomography is a valuable diagnostic aid. Frequently only bronchoscopy and bronchography lead to the correct diagnosis. Instead of a direct injection of lipiodol through a bronchial catheter the authors use tracheal instillation.

The authors discuss the anatomic topography of the middle lobe, paying particular attention to the interlobar incisures which interfere with the creation of a pleural symphysis. Pneumotomy of the right middle lobe always carries the risk of operative pneumothorax. Only operations on certain limited zones of the upper and lower lobes carry a similar risk.

The authors describe the variable character of the lesser incisura. Coalescence of the upper and middle lobes creates a great handicap for exeresis because a simple dissection in such cases is unable to liberate the middle lobe up to its pedicle.

Repeated punctures may be necessary to locate an abscess in the middle lobe because tomographic studies may visualize the lesion without establishing its exact relations to the thoracic wall. The best approach is from the front. Pneumotomy through the axillary line invariably exposes one of the incisuras. As a rule, the best approach is through the fourth or fifth intercostal space anteriorly. A resection of the fifth rib is usually sufficient but occasionally the fourth and sixth ribs must also be removed. Not more than from 4 to 5 cm. of a rib should be removed. The authors advocate two stages of pneu-

motomy with an interval of from 8 to 10 days between them. Even if the aspiration revealed an abscess, there is always the danger of surgical pneumothorax caused by the exposure of an incisura. If a pneumothorax is established before the discovery of the abscess, the danger of an infection of the pleura is relatively small. In such cases the pneumothorax should be aspirated and an attempt should be made to close the opening in the pleura. If the pleural cavity is opened at the time of the discovery of the abscess, the opening in the pleura should be promptly closed and proper drainage of the pulmonary focus should be established to avoid an infection of the pleural cavity.

In 4 of 5 cases of pneumotomy an operative pneumothorax was inadvertently established by the author by exposure of one of the incisuras. Attempts to provoke an interlobar symphysis by the insufflation of sterile talcum powder failed.

A surgical intervention is indicated only if one is dealing with a grave form of suppuration, without hope of a favorable spontaneous evolution. Sometimes direct aspiration through the bronchoscope and the application of cocaine to the bronchial mucosa may ameliorate the condition by facilitating drainage.

The authors' experience with lobectomy in the treatment of bronchiectasis showed that such a procedure is advisable only after the lesions became relatively dry. This can be accomplished by postural drainage in bronchiectasis but not in the case of an abscess, and therefore the authors prefer pneumotomy to lobectomy as far as the treatment of abscess is concerned. Furthermore, lobectomy of the middle lobe is technically much more difficult than lobectomy of the lower lobe because the separation from the upper lobe may be laborious and hemostasis of the pedicle may require a sacrifice of the lower lobe. Therefore, the authors recommend lobectomy only for chronic abscesses with pyosclerosis and associated bronchiectasis. Lobectomy may also be indicated if the process does not cease after pneumotomy and the suppuration and hemoptysis persist.

The authors employed pneumotomy in 4 cases, a single tamponade in 1 case and pneumotomy followed by lobectomy also in 1 case. One of the patients is still under treatment while the 5 others made complete recovery. JOSEPH K. NARAT, M.D.

Bérard, M., Galy, P., and Dumarest, J.: The Secondary Epithelialization of Cavities of Chronic Lung Abscesses, (*L'épithélialisation secondaire des cavités d'abcès chroniques du poumon*). *Presse méd.*, 1946, 54: 234.

In the surgical treatment of certain pulmonary suppurations, one of the major difficulties is represented by the absence of closure of the drained cavity, in spite of the disappearance of the local phenomena of suppuration.

The rigidity of the pulmonary parenchyma around the cavity, appreciable at the time of intervention

Fig. 1. Section of the wall. On the surface cylindrical epithelium is found lying on a slightly vascular fibrous tissue. Subepithelial cellular infiltration.

is considered the chief cause of persistence of the cavity.

The study of the inner lining of the walls, showing at times an epithelial border of the bronchial type, led the authors to a different interpretation of the facts. This inner wall—smooth and glistening like mother-of-pearl—is in contrast to the broken and irregular lining of the acute abscess cavity.

The shiny appearance of this inner lining of the drained cavity brought up the question in the authors' minds as to whether the original condition was a true abscess—a newly formed cavity in the course of suppuration in tissue which was formerly healthy—or the suppuration of a pre-existing cavity in the form of a congenital cyst or bronchiectasis. Diagnosis is often difficult even after microscopic examination of specimens of the wall removed at biopsy.

The presence of an epithelial covering of the bronchial type on the inner surface of the cavity is considered an important finding in favor of cyst.

The authors report some observations after microscopic study of tissue of the wall of a persistent cavity removed at biopsy 2 years after pneumotomy. At the time of pneumotomy it was noted, expressly, that the cavity contained pulmonary scarring, a sign of abscess of the lung. The contents of the most infected cyst are always liquid; the lining of the wall does not show scarring.

From the accompanying photomicrograph it can be seen that in one extremity of the section there is pseudostratified, ciliated epithelium. The epithelium lies on a distinct, well marked base of dense connective tissue with longitudinal bundles and little cellular infiltration. The capillary vessels are few in number. At the other extremity of the section, the fibrous tissue is more vascular. There are visible certain alveolar elements in the form of small cystic formations and a bronchus of fair size, lined by normal epithelium with much infiltration of the corium. Muscular elements are dissociated.

Similar observations were made by the authors while studying histological sections of the wall of a persistent cavity known to be due to suppuration of a pre-existing congenital cyst.

Theoretically, the wall of an epithelized chronic abscess does not contain smooth muscle, and glandular and cartilaginous structures of the bronchial type. In the congenital cysts and the bronchiectatic cavities, on the contrary, such structures will be found to be more or less numerous. The authors agree that these differences have great differentiating value, but are not absolute.

The mechanism of the epithelization of the chronic abscess cavity seems to the authors to be due to an epithelial growth which leaves the bronchus in drainage and advances progressively in the sticky pocket to cover the wall of the cavity. This epithelization is the most important factor in the passage to chronicity of the abscess cavity after pneumotomy.

From a therapeutic view it seems logical to attempt destruction of this epithelium. Such attempts run into great technical difficulties. The surgical decortication of the lining of the cavity exposes the patient to the danger of gaseous emboli by the entrance of air into newly formed capillaries in the wall. Chemical cauterization is possible, but has not been tried by the authors. Secondary lobectomy is indicated.

Early care of the foci of beginning pulmonary suppuration is the best prophylaxis of this formidable complication.

In résumé, the cavities of chronic abscess of the lung are often difficult to distinguish, both clinically and roentgenologically, from congenital cysts which have been secondarily infected and drained by pneumotomy. It is customary to consider that the histological examination of the lining of the wall permits a distinction between the lesions, as only the congenital cysts should present an epithelium of the bronchial type. Examination of the lining of the walls of certain pulmonary cavities, drained for a long time, allowed the authors to discover an epithelium on the surface in some of their cases in which the acute character of the initial lesion could not be doubted. So, an abscess cavity having passed to chronicity can secondarily epithelize itself. This is of importance in explaining the absence of closure and the cicatrization of some cavities after drainage.

BLACKWELL MARKHAM, M.D.

Watts, G. F., Clagett, O. T., and McDonald, J. R.: Lipoma of the Bronchus; Discussion of Benign Neoplasms and Report of a Case of Endobronchial Lipoma. *J. Thorac. Surg.*, 1946, 15: 131.

Because of the frequent presence of fat in tumors of the bronchus it was decided to study human bronchi in an attempt to answer three questions: (1) Is fat a normal component of the bronchus? (2) If it is, in what portion of the bronchial wall does fat occur? and (3) In which of the bronchi is fat present?

Blocks of tissue were cut from the bronchi and uninvolved parenchyma of 15 lungs that had been surgically removed from patients who had bronchogenic carcinoma. In addition, routine sections stained with hematoxylin and eosin, from the lungs

of 25 patients who died of brain tumors, were examined.

In the large bronchi fat always was present in the fibrous tissue external to the cartilage plates. Lesser amounts were found with equal frequency in the connective tissue (submucosa) between the cartilage and the muscular layer. In the latter position, fat was most frequently found near the cartilage plates; less often it approached the muscular layer. In the smaller bronchi fat was usually present in the walls in gradually decreasing amounts until the cartilages disappeared. The authors were unable to find fat in any portion of the bronchial tree which did not contain cartilage.

The treatment of fibromas, chondromas, hamartomas, and lipomas is the same. The procedure of choice is removal with bronchoscopic forceps, surgical diathermy, and local implantation of radon seeds, if necessary. Removal of pulmonary tissue need be done only when the tumor cannot be successfully treated through the bronchoscope or when suppuration in the pulmonary tissue distal to the tumor endangers the health of the patient. On the other hand, there is much disagreement concerning the proper treatment of the adenoma-cylindroma group. Those who consider these tumors strictly benign treat them just as they would the other benign tumors mentioned previously in this report. Others believe that the danger of local invasion, metastasis, hemorrhage, and local recurrence with bronchial occlusion outweighs the risk of primary pneumonectomy or lobectomy.

The authors' attitude toward the treatment of bronchial adenomas has been well summarized in a recent article by McDonald, Moersch, and Tinney. In brief, they favor conservative treatment when the adenoma is attached by a narrow pedicle and is movable, when it is situated close to the coryna, and when the general condition of the patient is poor. Lobectomy or pneumonectomy is preferred when the adenoma is situated in a bronchus that cannot be visualized bronchoscopically, when severe secondary pulmonary suppurative disease is present, when there is obvious evidence of peribronchial infiltration (of the adenoma), and when the adenoma has been treated endoscopically and tends to recur. Cylindromas are being treated in a similar manner until more is known about their growth potentialities. The authors are aware of the advantages of surgical extirpation and are now employing this method with increasing frequency.

Herbut, P. A., and Clerf, L. H.: Bronchogenic Carcinoma. *J. Am. M. Ass.*, 1946, 130: 1006.

The method of examination of bronchial secretions for cancer cells is presented not with the idea of finding a substitute for the already well established and highly efficient methods used in the diagnosis of pulmonary carcinoma, but as an adjunct to be used in conjunction with these methods. By the method outlined it is hoped that the central, peripheral, or pulmonary neoplasms will be diagnosed at the time

of the first bronchoscopy without losing a valuable month or two waiting for an x-ray shadow to increase or decrease in intensity in order to be certain that a lesion is or is not neoplastic. By that time it might be too late.

In cases in which a tumor was visualized endoscopically it was made certain that the neoplasm was not traumatized with the bronchoscope, in order that only spontaneously sloughed material might be examined.

The aspirator was washed with a small quantity of saline solution only when the amount of secretion was too scanty to reach the collector. As soon as the material was obtained it was sent to the laboratory where smears were made immediately, and while still wet were fixed in equal parts of 95 per cent alcohol and ether, and stained by the Papanicolaou technique.

Thin smears are more valuable, for in these all cells can be adequately studied. In preparing the smears, the material was placed in the center of the slide and gently crushed with another slide, care being taken that any granules which may have been present did not escape peripherally. Because of the inequality of the distribution of the cancer cells, an arbitrary figure of 5 smears from each secretion was adopted, and in a few instances as many as 15 smears were prepared.

The secretions were quite characteristic, although not necessarily pathognomonic. The color ranged from gray and watery to somewhat creamy and opaque, but invariably the secretion was either streaked with or diffusely mixed with bright red, pink, or dark brown partially disintegrated blood. It was always tenacious and adhered closely to the side of the collector and glass slide.

One must first become thoroughly familiar with the noncancerous elements in bronchial secretion.

In secretions containing cancer cells, there is a certain appearance which gives one the impression that the preparation should contain cancer cells. The leucocytic elements are in abeyance or entirely absent. The slides appear "cleaner" than do those, for instance, from bronchiectatic cases. Pavement cells are often increased when the tumor is of a squamous cell variety. The erythrocytes are usually fairly abundant.

The following separate groups of cancer cells have been recognized in bronchial secretions:

1. Clusters of cells which are present in squamous cell carcinoma. They are seen as a mass of closely packed, relatively large cells whose cytoplasm stains an orange red and whose nuclei are large and dark blue. Cilia are never present. At the periphery there are usually encountered a few detached single cancer cells. These cells are quite well differentiated and so do not appear as "wild" as do the cells of the more anaplastic tumors.

2. Large irregular single cells found in the more differentiated tumors and in those with adenomatous formation. When the tumor is less well differentiated, in adenomatous formation or a combination of

the two, single cancer cells are found in the secretions. The nuclear-cytoplasmic ratio is increased over normal. The nuclei are single or multiple and usually are extremely bizarre. Nucleoli are not always demonstrable.

3. Smaller more uniform cells present in the so-called oat-cell carcinoma. They are best identified by their size and by the fact that although the cells are similar, there are definite variations in the shape of the nuclei from cell to cell.

A diagnosis of carcinoma can be made on finding a single cancer cell. Usually if there is one cancer cell present there are others also. It can be stated as axiomatic that any cell or group of cells bearing cilia are not cancerous. When bizarre single cells are encountered, there is no question of the process being cancerous.

When one is in doubt as to whether a cell or group of cells are cancerous, the chances are they are innocent. Lymphocytes, basal cells, and macrophages may be confused with cells from an oat-cell type of carcinoma.

In 30 consecutive cases of primary pulmonary carcinoma, cancer cells were demonstrated in 22, or 73 per cent of the cases. In the same series a positive morphological diagnosis, from a study of tissue removed endoscopically, was obtained in 11 cases, or 36 per cent. Cancer cells were present in secretions from 7 cases in which bronchoscopy was negative.

LEE PULLEN, M.D.

Allison, P. R.: Intrapericardial Approach to the Lung Root in the Treatment of Bronchial Carcinoma by Dissection Pneumonecctomy. *J. Thorac. Surg.*, 1946, 15: 99.

A technique of individual ligation of pulmonary vessels after wide opening of the pericardium has been evolved, with the result that those bronchial growths closely set between the hilar structures, those surrounding, or even adherent to, the pulmonary vessels, and those in which the primary growth or secondary glands are adherent to the pericardium, can now be dealt with more radically. When the growth is peripherally placed and the hilar structures are separated by soft glands and areolar tissue, the usual dissection outside the pericardium presents no difficulties. If the vessels are felt stretched over masses of growth, or if neoplastic tissue is felt so near to the pericardium that a good margin of tissue cannot be obtained beyond it, intrapericardial dissection offers a quicker, safer, easier and, at the same time, more radical operation.

The chest is opened by either of the two recognized approaches for lung carcinoma: the anterior incision or the posterolateral incision. The immediate results in surgical removal of the lung for carcinoma depend very much on the spillover of septic secretions into the good lung, and it is therefore of great advantage if the affected bronchus can be occluded either by clamp or strong ligature before much manipulation of the lung takes place. More often this can be done easily by the posterolateral approach.

Left Side. The left phrenic nerve is crushed as it crosses the aortic arch. An incision about $\frac{1}{2}$ inch long is then made in the pericardium immediately in front of, and parallel with, the phrenic nerve. This incision is extended backward over and below the lung root, dividing the phrenic nerve and accompanying vessels which have been understitched by tied. When the outer edge of the pericardium is retracted, the most obvious vessel is the anterior superior pulmonary vein. The reflection between the two veins is easily perforated with curved scissors and the opening enlarged so that the finger can be passed around the vein. The vein should then be hooked forward while the serous reflections are still further divided, both toward and up to the parietal pericardium and inward to the auricle. In this way the length of the vein available for ligature and division inside the pericardium is ample. Number 6 silk ligatures are applied, and then the vein is transfixed between the ligatures, one adjacent to each ligature. The vessel is then divided between the transfixion. The inferior vein is treated in a similar manner.

To isolate the pulmonary artery, the pericardial incision is prolonged upward to the anterior aspect of the artery. The finger can then be passed around the superior and posterior aspects of the vessel to show below, covered by the serous reflection. This reflection is divided and the artery is then free to be treated by double ligature and stitching, as already described for the vein. On the left side the inferior vein may present some difficulty if the anterior approach is used, for it is overlaid by the ventricles, but on the right side it is easily accessible by either approach. The fibrous pericardium over the left main bronchus is then incised. The glands and fibrous tissue from the bifurcation of the trachea, and from within the arch of the aorta, are drawn down. The bronchus is divided and closed by a single terminal continuous stitch. The remaining pericardium behind the lung root is then divided and the lung is removed. This last incision should be well toward the middle line so that the mediastinal tissue between the pericardium and the esophagus can be stripped down in continuity with the glands at the bifurcation of the trachea.

In cases in which a growth occurs in the left upper lobe, and especially when the posterolateral approach is used, it may be easy first to cut the lateral pulmonary ligament and then to divide the posterior inferior vein outside the pericardium. If malignant tissue involves the superior vein, it may be necessary to dissect the vein and upper border of the auricle off the main pulmonary artery and to make the section through the auricle itself rather than divide the veins separately. In this event it is useful to tie a ligature of stout colostomy silk around the isolated part of the auricle. Three traction sutures of fine silk are then inserted in the auricular wall, distal to the ligature. Clamps are applied still more distally and the auricle is divided between the clamps and the traction sutures and finally stitched up with

continuous fine silk. The traction sutures may then be lightly tied or removed.

Right Side. The incision of the pericardium in front of the lung root passes backward above, dividing the phrenic nerve and vessels and reaching the angle between the superior vena cava and the right pulmonary artery. Here the serous coat is reflected on the under surface of the artery, leaving a fornix in front and behind. The fibrous pericardium, as it plays out in the angle between the two vessels, is divided, and the serous reflection of the anterior fornix is cut. The finger can then be passed through the posterior fornix into the postcaval recess, and a long length of pulmonary artery exposed. It is doubly ligatured, stitched, and divided. The pulmonary veins on the right side sometimes join so soon after entering the pericardium that they are more easily treated as a single vessel. The vessel is really a part of the left antrum and has a fairly thick muscular wall. Below the inferior pulmonary vein the double layer passing on to the inferior vena cava is divided. Access to the posterior surface of the antrum is then possible, and after the serous reflections above the superior vein have been divided, it can be treated in the manner described for the left side. It may be necessary, in order to leave enough room for division, to omit the distal ligature and apply a clamp. In such circumstances it has usually been considered wise to tie off the pulmonary artery before dividing the veins, so that if the clamp slips, the loss of blood is only that which would be removed with the lung.

On either side no attempt is made to close the pericardial sac. It is considered an essential part of the operation that the pericardial sac be left in wide communication with the pleural space, into which it drains freely. This applies whether or not contamination of the pleura is thought to have occurred. It may be found necessary to insert one or two sutures to prevent prolapse of the heart or part of the heart into the pleura, otherwise impairment of cardiac function might occur from the strangulating action of the cut edge of the pericardium.

The most important points in bronchial closure are section of the bronchus as close as possible to the trachea, simple terminal suture, and a good cover of pleural membrane with mediastinal tissue which must be stitched to the stump well above the line of bronchial suture.

The above technique was used in 10 patients who were otherwise considered to be inoperable. Five of these cases came to autopsy. The remaining 5 patients are still alive.

The author states that no conclusion can be drawn about the relative merits of extrapericardial and intrapericardial dissection in respect to the end results. Sepsis seems to be no contraindication to opening the pericardium as long as it is left in free communication with the pleural space afterward. The pericardial sac appears to drain into the pleura and become sealed off in from 2 to 3 days.

LEE PULLEN, M.D.

Mandeville, F. B.: Roentgen and Clinical Problems In So-called Solitary Metastatic Tumors in the Chest. *Am. J. Surg.*, 1946, 71: 669.

Because the tremendous acquisition of skill and experience by thoracic surgeons has increased the responsibilities of the radiologist in the examination and diagnosis of chest tumors, the author's object is to consider the management of solitary metastatic tumors of the chest without drawing any rigid or final irrevocable conclusions.

Five cases seen during his x-ray experience were subsequently operated upon and illustrated that thoracic surgery has reached a state of perfection in which survival after operative removal of metastatic chest tumors is obtainable. In 1 instance a primary hypernephroma was missed until the pathologist had studied the sections of an excised chest tumor assumed to be primary. Subsequent intravenous pyelography showed an enormous left kidney tumor with poor function and very poorly outlined and deformed pelvis and calyces. Within 6 months the lungs showed multiple oval metastatic nodules and death soon followed. Error in this case was disastrous and shows how the responsibilities of the radiologist have increased.

Personal communications of many thoracic surgeons over a period of years emphasize that in certain cases in which the primary tumor has been removed and an apparently single late metastatic lesion appears, operative intervention is being considered as a chance possibility of completely eradicating the disease. Relief of pain, alleviation of respiratory distress, and removal of a focus which might give rise to tertiary metastases have been other arguments in favor of surgery.

Eight reports of surgical removal of apparently solitary metastatic chest tumors have been abstracted from the medical literature.

A most discouraging argument has been the lack of enthusiasm shown by pathologists as a group for these procedures, since proved solitary metastatic tumors in the chest appear to be rare at autopsy and unlikely in the light of Batson's contribution on the vertebral veins as a channel for spread.

In considering exploratory thoracotomy it is difficult to differentiate benign from malignant tumors of the chest by roentgen means alone, and it is also difficult to differentiate many primary from solitary metastatic tumors with x-rays.

We lack knowledge of the natural history of primary tumors and their metastases which makes prognosis difficult when they are treated surgically or when they are not treated. Metastases sometimes manifest themselves from 5 to 15 years after proof of existence of the primary cancer.

Other means than surgical, such as radiation therapy, are inadequate in dealing with primary or metastatic tumors of the lung.

The many problems of solitary metastatic tumors of the chest remain unsolved, but the author calls attention to treatment which is as yet of a highly experimental nature.

LYNN JOHNSON, M.D.

Santas, A. A.: The Technique of Lobectomy, with Especial Reference to the Individual Ligation of the Parts of the Pedicle (Técnica de la lobectomía, con especial referencia al procedimiento de la ligadura individual de los elementos del pedículo). *Rev. Inst. clin. quir.*, B. Aires, 1945, 21: 421.

Santas considers that the evident progress during the last few years in the field of thoracic surgery has been due to several factors such as the proper anesthesia, the better systematization of patients, the positive pressure and tracheal intubation, and the preventive treatment of shock. He describes the anatomy of the bronchi and the arteries of the lungs.

According to his experience he has found the individual bronchovascular ligation to be the elective procedure in the lobectomy operation. In doing the individual ligations of both the bronchi and vessels he found that the lobectomy was more complete and that the chances of cicatrization without infection were greater. The pleuralization of the stump and the proper drainage during at least from 48 to 72 hours are measures of importance for the success of the operation. The operating technique of lobectomies in general as well as of lobectomies concerning each particular lobule are described. The indications in general are discussed.

The anesthesia most commonly used is cyclopropane-ether given by tracheal intubation. The transitory phrenic inhibition is made by novocain injection in the neck or, if paralysis of the diaphragm is not essential, the opening of the thorax is made by an intercostal incision or by resection of one or more ribs.

Once the thoracic cavity is opened, gauze wet with saline solution is placed in the borders of the wound. The dissection of the incisura of the lung should be complete. Before dissection of the hilum the vascular elements should be recognized to avoid hemorrhage. Before the bronchi are approached the pleural cavity should be isolated to avoid its contamination. The bronchi are ligated with a U ligature and section of the bronchi is done with an X ligature. Unnecessary trauma of the pleura should be avoided. It is considered good practice to add sulfonamide powder to the pleura before the wound is closed. Proper drainage during the first 48 to 72 hours is indicated.

After the pleuralization is done expansion of the lung is initiated. The suture of the different layers of tissues of the operative wound is done methodically, and an attempt is made to close the pleural cavity entirely.

WILLIAM E. RICKETS, M.D.

ESOPHAGUS AND MEDIASTINUM

Leegaard, T.: Corrosive Injuries of the Esophagus; with Particular Reference to the Treatment of Acute Corrosive Esophagitis. *J. Lar. Otol.*, Lond., 1945, 60: 389.

In the Ear, Nose, and Throat Department of the Rikshospital, Oslo, 29 patients in all, with recent corrosive injuries and strictures of the esophagus,

were admitted during the 10 year period from 1933 to 1942. Of these 52 were children between 1 and 3 years of age, and 50 were children between 4 and 10 years of age.

Since May 5, 1943, a total of 52 such patients have been treated. Thirty-four of these 52 had fairly recent injuries, and 30 were children under the age of 3.

The increase in the cases is apparently due to the increased use of chemical washing materials during war conditions. Perhaps the children's unsatisfied craving for sweets also plays a role.

Corrosive injuries of the esophagus may be seen in patients of all ages. In adults, accidents, carelessness, and, perhaps most often, attempted suicide are responsible. In children they are due almost constantly to negligence on the part of the relatives.

Corrosive injuries may arise from swallowing acids and alkalis, but in the majority of cases they are due to the careless use of chemical washing materials, solutions of lye, and, more rarely, caustic soda in substance or washing powders. In some cases the author has seen severe corrosive injuries in children who have drunk essence of vinegar, i.e., concentrated acetic acid.

The symptoms depend on the concentration of the corrosive substance and on the amount swallowed. A single gulp, especially in children, can produce very severe injuries.

The patients have burning, smarting pains in the mouth and throat. Edema and injection of the mucosa appears, and eventually white corrosion marks are found on the lips, tongue, palate, and in the throat. Edema in the laryngeal aperture may cause respiratory obstruction. Difficulty in swallowing appears with marked salivation and vomiting, which may be blood stained.

Somewhat later, pains in the chest, radiating to the back, occur and indicate rather a deep lesion of the esophageal wall. In such cases fever is also observed and it may be quite high. Other toxic symptoms, with a state of severe generalized exhaustion, may be present and lead to death in the course of a day or two. In some cases acute corrosive esophagitis may lead to serious developments even after the immediate danger is over.

In deep corrosion of the esophageal wall, periesophageal changes, perforation of the wall, purulent esophagitis, and mediastinitis appear and may become circumscribed, but sometimes they break through to the pleura and pericardium, and produce purulent pleurisy and pericarditis. Rupture into the trachea or bronchi is also seen.

If the patient does not die as the immediate result of the accident, the acute symptoms subsequently recede in most cases, the patient is again able to begin swallowing, first fluids, then soft food, and often any kind of food. After 3 or 4 weeks the difficulty in swallowing recurs, and the increasing after-effects of corrosion produce a more or less severe constriction of the gullet. In a great many cases the patients, in spite of treatment, suffer trouble for the rest of their lives. Food must always be chewed

finely, since even small pieces may stick, particularly pieces of apple, and potato. The state of nutrition may suffer because of this, and the resistance to disease may be lowered. Moreover, there is the continuous danger of fatal complications produced by lesions resulting from the passage of bougies and attempts to remove foreign bodies.

Diagnosis is usually easy. It may, however, be difficult to determine the localization of the corrosion and its depth.

The localization of the stricture due to corrosion in 30 patients, whose case histories contain sufficient relative data, was as follows:

Esophageal mouth	2
Between the mouth of the esophagus and bifurcation	9
Bifurcation	7
Between the bifurcation and the hiatal region	7
Hiatal region	3
Whole esophagus	2

From this, it appears that the lower half of the esophagus is more frequently attacked than the upper. No special attraction for the physiologically narrow places appears to be indicated in this series.

The prognosis is not particularly good. However, the mortality figures vary considerably among the different writers. Von Hacker gives the mortality as between 40 and 50 per cent, Billroth 38 per cent, Belinoff 27 per cent, and Erdelvi between 20 and 23 per cent.

In cases of severe corrosion most deaths occur during the acute stage, and the patients who are "cured" with stricture formation are exposed to constant dangers later. In some a poor state of nutrition results in diseases dangerous to life. In all, perforation may follow at any moment as a result of passing bougies. Impacted foreign bodies also bring the danger of complications.

Of the 52 patients treated by the author, 6 died subsequently, 2 of 34 treated in the acute stage, and 4 of 18 treated for stricture.

The prognosis with regard to the functional result is dependent partly on the degree of action of the corrosive, partly on treatment.

Dilatation of esophageal strictures has been carried out for several hundreds of years. The essential point is to begin treatment before the stricture has appeared, before the scar is formed. It is necessary to prevent the stricture, and therefore the scar formation must be controlled. The risk of this early treatment does not appear to be great, judged by the fairly extensive literature which has been written on this subject. However, even if there is, generally speaking, unanimity in regard to the advantage of this early treatment, considerable difference of opinion still reigns as to when it should begin and how it should be carried out.

Treatment in the form of daily passage of soft bougies should begin from 2 to 6 days after the injury. Some workers, however, consider that the beginning of the second week is the most favorable time.

The best treatment of the deeply penetrating necrosis is by means of the use of a retained tube, which is accomplished by the help of an external esophagotomy.

In view of earlier writings and on the basis of the treatment of his own cases, the author recommends that for adults and older children the daily passage of soft bougies should be used in the cases of lesser stricture. In severe cases external esophagotomy is done and a tube is introduced.

A retained catheter introduced through the nose is used for small children in the first year of life for the milder cases, and external esophagotomy with a retained tube is resorted to in severer cases.

This is illustrated with records of the case histories of patients in the different categories.

Subsequently, the treatment of cases in which strictures are already established is briefly discussed. In individual cases dilatation by diathermy of circumscribed scarring can be readily accomplished. This is illustrated by an example.

The author's own material is summarized. It consists of 52 patients, 34 with the diagnosis of acute corrosive esophagitis and 18 with the diagnosis of stricture of the esophagus. External esophagotomy was performed on 15 occasions. In the follow-up of the first group there were 26 cures, 2 cases which were much improved, and 2 deaths. In the follow-up of the second group (strictures) there were 3 apparent cures, 7 cases with great improvement, 1 case without change, the patient dying later, and 3 deaths.

ERNEST E. ARNHEIM, M.D.

Johnstone, A. S.: *Dysphagia Due to Causes Other Than Malignant Disease*. *Edinburgh M. J.*, 1946, 53: 160.

This subject was chosen for the Honeyman Gillespie lecture, which was delivered in the Royal Infirmary on June 7, 1945. All of the causes of difficulty in swallowing other than malignant disease were discussed. The author divided the causes of dysphagia according to the different decades of life. He stressed that difficulties in swallowing may arise from disorders of the complicated physiologic mechanisms involved, from obstructions within the lumen of the esophagus, or from pressure on the outside. He discussed the physiology of swallowing.

In the first decade of life congenital atresia is a rare condition but should be suspected when a newborn infant chokes, coughs, or turns blue on taking its first and subsequent feedings. Eighty per cent of the cases discussed by the author showed a fistula below the lower esophageal segment and the trachea, or a main bronchus. Congenital stricture, web, shortening, and spasm may become manifest during the first few years of life. Boys are more frequently affected than girls.

During the second decade of life a congenital stenosis may become apparent. The roentgenograph will show the esophagus to be dilated above the stenosis. Frequently a foreign body will be present at the point of stenosis and has been the cause of the show-

Fig. 1. a, (B) Base of tongue bulging backward and downward as it propels the bolus. (E) Epiglottis turned over. b, Lipiodol filling the esophageal "cul de-sac." Note air in stomach and bowel denoting tracheoesophageal fistula. c, Typical congenital stenosis in adolescent. Shortening of lower segment. Gastric mucosa seen passing through the esophageal hiatus. d, Early stage of achalasia. Gastric mucosa seen in narrowed segment. e, Early stage in achalasia. Note the serrated outline due to small, irregular contractions; wide dilatation of upper segment; thickening

of the wall. f, Shadow on right of mediastinum caused by dilated esophagus. Bilateral atelectasis of the lower lobes with bronchiectasis. g, Shelflike defect in barium column due to web. h, Peptic ulcer of esophagus. Crater seen in narrowed segment with dilated esophagus above and gastric pouch below. (Semierect position.) i, Irregular contractions of circular fibers producing "functional diverticula." j and k, Filling defect due to simple tumor. Ring shadow; lobulation; smooth external surface. l, Esophagus displaced anteriorly by rudimentary left aortic arch.

ing up of the stenotic area. Also during this decade the accidental drinking of a corrosive substance seems to occur more frequently, and the degree of dysphagia from acute esophagitis may be very severe.

The most common cause of dysphagia in the third decade is achalasia in its earliest stages. Roentgenology provides evidence in support of the current theory that achalasia is caused by a neuromuscular lesion. One finds a spasm affecting a segment at the lower end of the esophagus from 1 to 2 cm. long. This segment involves the cardia and the cardiac ampulla, or that part of the esophagus lying in and below the diaphragmatic hiatus.

In the fourth and fifth decades we find dysphagia occurring in middle aged women suffering from anemia of the hypochromic, microcytic type. The signs of Patterson-Brown Kelly, and the Plummer-Vinson syndrome, with fissured lips, sore tongue, koilonychia, splenomegaly, and achlorhydria may be present, and any one of these should warn the radiologist to pay special attention to the post-cricoid region. It is interesting to recall that Vinson considered the dysphagia to be hysterical, Brown Kelly believed it was due to spasm, and Patterson suggested that a web might exist as well as spasm.

Careful fluoroscopy may reveal two things—a spasm at the upper end of the esophagus and a web. The first, a narrowing in the post-cricoid region about 1 to 2 cm. long, is seen in the anteroposterior view. It appears to be caused partly by contraction of the lower fibers of cricopharyngeus muscle and partly by the terminal bundles of the muscularis propria of the esophagus. The second is a small projection from the anterior wall which, as it becomes larger, juts out into the column of barium like a thin shelf. The webs may be multiple and are commonly situated in the post-cricoid area but may be found at a lower level.

During the fifth, sixth, and seventh decades the following causes of dysphagia are most common: peptic ulceration of the esophagus and a partial thoracic stomach; pharyngeal diverticulum, tertiary contractions with functional diverticula and benign tumors and nervous lesions; and a group of disorders such as bulbar paralysis, botulism, diphtheria, and myasthenia gravis, which may bring about dysphagia by paralyzing one or more of the muscles of deglutition or by causing loss of sensation. Also extrinsic pressure from cardiovascular causes may result in dysphagia.

PAUL MERRELL, M. D.

Johnstone, A. S., Harper, R. A. K., McLaren, J. W., and Grossmann, M. E.: Symposium: Nonmalignant Conditions of the Esophagus. *Brit. J. Radiol.*, 1946, 19: 101.

The symposium presented is made up of four separate papers by the authors, in the order named.

The author of the first paper discusses some of the more unusual causes of dysphagia. The subject is introduced by a rapid but rather detailed description of the esophagus from the standpoint of anatomy, as well as physiology, and some of the newer thoughts

are pointed out. The condition first described is referred to as post-cricoid web. Just how the condition arises is not clear, nor is its relation to associated spasm. Its association with a microcytic hypochromic anemia in middle-aged women, accompanied by other deficiency signs, should forearm the radiologist. Although response to iron is usually notable, further examination to exclude malignant disease is recommended.

Functional diverticula may be produced possibly as a result of abnormal distribution and sequence of esophageal contraction waves. The pathogenesis and the theories advanced to explain these findings are discussed.

Congenital defects of the esophagus are referred to, but the congenital narrowing usually at the level of the bifurcation of the trachea, more common in male children, but occasionally persisting throughout adult life, is developed in some detail.

Peptic ulceration and partial thoracic stomach are discussed. Some points of differentiation between an esophagitis and definite peptic ulceration are presented. The matter of a congenitally short esophagus, epiphrenic pouch, small hiatal hernia, or a definite phrenic ampulla is given considerable attention. Numerous illustrative roentgenograms are appended.

The author of the second paper discusses a large variety of conditions, both congenital and acquired, including those of traumatic, inflammatory, and ulcerative etiology, as well as tumor, anatomical displacements, and such miscellaneous conditions as varices, diverticulum, achalasia, etc. The discussion of each point is rather brief and somewhat in summary, but is supported by good roentgenographic demonstrations.

The third paper refers to a "corkscrew" type of esophagus, as described by Johnstone and Templeton. Some discussion of the etiology is given and good roentgenographic reproductions are appended. Another case is briefly presented of regurgitation into the esophagus in face of a normal emptying time of the stomach in an infant.

The fourth paper concerns 2 cases of achalasia, illustrating the beneficial effects of treatment by octylinitrite with special reference to its action on the cardiac sphincter. The third case reviewed presented a congenital, short esophagus with two diverticula of the lower third of the esophagus, believed to be congenital in nature, and associated with a peptic ulcer of the lower end. A fourth case presented a large chronic duodenal ulcer, also a large chronic ulcer in the lower part of the esophagus, from which a small perforation led into the left auricle. Of course this latter complication was believed to be of short duration.

HIRAM T. LANGSTON, M.D.

Blades, B.: Mediastinal Tumors. *Ann. Surg.*, 1946, 123: 749.

During a period of 3 years 114 patients were operated upon for mediastinal tumors in the Army

Thoracic Surgery Centers in the United States. No neoplasms of lymphoid origin—lymphosarcomas, Hodgkin's disease, or lymphocytoma are included in this series unless the surgical intervention resulted from an erroneous diagnosis. There were 94 benign and 15 malignant tumors. In 5 cases aneurysms were found.

Twenty-three bronchiogenic cysts were removed from the mediastinum. Up to 1945, only 35 cases were reported in the literature. These cysts are located at almost any site along the tracheobronchial tree. Commonly they occupy an anterior or posterior position at the bifurcation of the trachea. Mild substernal pain and cough are the only symptoms; in this series 21 of the cysts were asymptomatic. The rest were detected on x-ray examination. Antero-posterior and lateral films are necessary to differentiate the mass from teratoid or primary nerve tumors. On lateral views, the mass does not occupy the extreme posterior position of primary nerve tumors, and its shadow is less distinct than that of teratoid tumors. The mass usually moves with swallowing as it is attached to the trachea. Bronchograms and esophageal studies often aid in the diagnosis. Grossly, these masses are round or ovoid and are usually attached by a stalk to the carina or bronchus. They may vary from thin walled tumors filled with clear fluid to almost solid neoplasms. It is believed these cysts are developmental abnormalities resulting from a pinching off of a diverticulum of the foregut near the tracheal bud or representing a secondary development of the tracheal bud. Microscopically, one sees any or all tissue normally present in the trachea and bronchomucous glands, cartilage, connective tissue and smooth muscle. Stratified squamous or ciliated pseudostratified epithelium may line the cyst. Surgical removal is the treatment of choice as the pre-operative diagnosis is uncertain, the cysts may become infected, increase in size and cause pressure symptoms, or they may potentially become malignant.

Twenty cases of teratoid tumors—dermoids and teratomas—were operated upon, and of these 6 were highly malignant. Teratoid tumors are relatively common, more than 245 being recorded in the literature. They produce sharp and obvious x-ray shadows and are easily detected. Cough and chest pain are the most common symptoms. A case report of a tumor involving the right middle lobe of the lung and causing hemoptysis is given. Teratoid tumors also may cause pressure effects leading to cough, dyspnea, and enlargement of the neck veins. On x-ray examination the characteristic anterior mediastinal position is suggestive, but unless bones or teeth are visible a positive diagnosis is impossible. Only in 3 of the 20 cases was the tumor not in the anterior mediastinum. These tumors may range from thick walled, fluid filled cysts to solid tumors, and vary in size and shape. The tumors frequently contain ectodermal derivatives such as hair, teeth, or skin. It is believed they originate from cell rests. Microscopically, elements of endoderm, ectoderm,

and mesoderm may be found. Often combinations of tissue from the digestive or respiratory tract, thyroid, or thymus are found. Surgical removal is the treatment of choice, since malignant degeneration is not uncommon. X-rays are ineffectual. In the literature 12.9 per cent are reported as showing malignant change. It is emphasized that once malignancy develops, successful treatment is almost impossible.

Twenty-nine benign neurogenic tumors of the mediastinum—neurofibromas, ganglioneuromas, and sympathicoblastomas—were successfully removed. One case of neurogenic sarcoma was explored and found inoperable. These tumors are more common, 105 being reported by Kent from the literature. Usually these tumors are asymptomatic. If certain nerves are involved pain or a Horner's syndrome may be present. Definite clinical manifestations usually indicate a malignant change. On x-ray examination these tumors are round, spherical, or lobulated, and occupy an extreme posterior position. Careful roentgenograms of the spine for bone erosion may indicate the presence of a dumbbell tumor—a tumor arising in the intervertebral foramen and extending both into the spinal canal and anteriorly into the posterior mediastinum. This spinal canal involvement may be very difficult to detect even at operation. Usually the intercostal and sympathetic nerves are the site of origin. Microscopically, the picture of these tumors varies widely. Often there is a preponderance of fibrous tissue (ganglioneurofibroma) or of ganglion cells (ganglioneuroma). Lack of differentiation from cellular myxomatous tissue produces a microscopic picture of a myxoid neuroma. Malignant changes are often difficult to determine, and these tumors will recur if incompletely removed. About 37 per cent of primary nerve tumors undergo malignant degeneration, so prompt surgical excision before malignant changes occur is the only hope of cure. X-ray treatment is futile.

Ten pericardial cysts are included in the series; all were asymptomatic. They usually show an anterior position on the roentgenogram. These cysts are anomalies of pericardial development. They are thin walled cysts lined with mesothelial or endothelial cells and lying in contact with the anterior chest wall and the parietal pericardium. Operation is recommended to establish the diagnosis.

Six thymic tumors (4 benign) were studied. One was associated with advanced myasthenia gravis. Four of the patients were asymptomatic, the tumors being discovered on x-ray examination. There are no definite criteria for x-ray diagnosis. In many cases the tumor tends to maintain the shape of the thymus. It is usually seen quite plainly in the anteroposterior projection, but is not so apparent in the lateral view even when it has caused distortion. These tumors lie subinternally in the anterior mediastinum. They are of reddish brown color and have a varied microscopic picture. If benign they look like normal thymic tissue. If malignant they may look like a malignant lymphoma, epidermoid carcinoma,

or a teratoid tumor, or they may be made up of endodermal thymic reticulum cells. If these lesions fail to respond to x-ray therapy, surgical excision is recommended.

Only 4 mediastinal lipomas were removed. They are rare, only 40 being recorded in the literature. They may cause pain, dyspnea, and cough, according to their size and location. On x-ray examination one can sometimes make the diagnosis if the shadow of the mass becomes more opaque toward the periphery. These tumors may be entirely confined within the thoracic cage, may be intrathoracic and extend into the neck, or they may be intrathoracic with an extrathoracic extension. Their microscopic appearance is characteristic. Surgical removal is desirable as these tumors often grow to huge size.

Other mediastinal tumors found were 1 fibroma, 1 thyroid adenoma, 2 tuberculomas, 1 esophageal cyst, and 1 osteochondroma of the mediastinum. Three cases of inflammatory lymph nodes were discovered on exploration, and a Boeck's sarcoid was diagnosed after biopsy.

Fourteen malignant tumors were found—6 malignant teratomas, 2 thymomas, 1 neurosarcoma, 2 lymphoblastomas, and 4 cases of Hodgkin's disease. In only 3 cases was it possible to remove the tumor, and in each case the tumor was a Hodgkin's granuloma. A case is presented in which a posterior mediastinal tumor of unknown origin was removed and proved to be Hodgkin's disease. In the other cases the tumors had hopelessly involved the adjacent structures and biopsy only was carried out.

There is no infallible method of determining the exact nature of a mediastinal mass preoperatively.

Most benign and some malignant tumors of the mediastinum are amenable to surgical removal. Refinement in operative and anesthetic techniques now have made exploration of the chest safe. It is usually possible to make a reasonably accurate diagnosis of mediastinal tumors of lymphatic origin. These are with few exceptions the only mediastinal tumors which will respond to x-ray therapy, so a test dose of x-rays for approximately a month can be tried. If the tumor fails to change in size, surgical exploration to determine its exact nature should be performed. Continued injudicious radiation may be disastrous.

In 114 exploratory thoracotomies there were no deaths attributable to the exploratory operation. Three cases developed suppurative pleuritis which healed promptly with adequate drainage. Therefore operation should not be delayed until signs and symptoms of pain and enlargement of the tumor are present because usually at this time the opportunity for successful removal will be past.

There is no agreement as to the proper surgical approach, the posterolateral, anterior, and lateral being used. If technical difficulties are anticipated the lateral or posterolateral is preferable. Properly administered intratracheal anesthesia has been found to be essential for exploration of the chest and mediastinum.

The author recommends the universal application of routine x-ray examination of the chest in individuals of all ages in order that early diagnosis can be made and adequate surgical treatment of intrathoracic tumors can be instituted.

ROBERT R. BIGELOW, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

D'Abreu, F., and Humble, J. G.: Mesenteric Venous Thrombosis; Recovery after Resection with Heparin. *Lancet*, Lond., 1946, 1: 534.

A successful case of resection of the small intestine for mesenteric venous thrombosis is described.

A new method of titrating the coagulability of the patient's blood, with heparin solutions of decreasing strength, is preferred to the estimation of the coagulation time.

The use of heparin is urged in cases of thrombophlebitis when dangerous complications are feared.

JOHN J. MALONEY, M.D.

Mattson, H.: Use of the Rectus Sheath and Superior Pubic Ligament in Direct and Recurrent Inguinal Hernia. *Surgery*, 1946, 19: 498.

A method of hernioplasty is described wherein a flap of the anterior rectus and pyramidalis sheath is turned down and sutured to the superior pubic ligament. Such a procedure is believed to be indicated in (1) direct inguinal hernias, (2) indirect inguinal hernias with weak and redundant fascia in Hessel-

Flap is turned back

Fig. 1. Illustrating suture of the rectus sheath to the superior pubic ligament.

bach's triangle, (3) recurrent inguinal hernias operated on previously by other methods, and (4) femoral hernias.

SAMUEL KAHN, M.D.

GASTROINTESTINAL TRACT

Beck, W. C.: Acute Gastroduodenal Obstruction (Dilatation). *Arch. Surg.*, 1946, 52: 538.

It is the author's opinion that the severe symptoms associated with acute gastroduodenal dilatation are almost invariably due to obstruction in the duodenum. The exact site of the obstruction is usually at the point where the superior mesenteric artery crosses the duodenum. Predisposing factors of acute gastroduodenal dilatation include emaciation, ptosis of the viscera, a short mesentery, lordosis of the lumbar portion of the spine, and collapsed intestines, such as are seen in wasting disease. A chronic obstruction of a mechanical type may be transformed into an acute one. The most prominent symptom is vomiting, which is copious in amount and associated with nausea. Vomitus is bile-stained to dark green. The amount of gastric contents aspirated through a stomach tube is usually remarkably large. Pain is not a prominent feature, but when present is situated in the periumbilical area and does not radiate. The abdomen becomes distended in some cases but is flat in others, and abdominal tenderness is either entirely absent, or diffuse and slight. The most striking part of the physical examination is the general appearance of the patient, which is usually one of pronounced loss of weight and emaciation.

The roentgenogram is diagnostic. The scout film reveals pronounced dilatation of the first and second parts of the duodenum. Since the duodenum lies on a different anteroposterior plane than the stomach, the lateral projection is an important one in differentiating dilatation of the two organs. All the roentgenograms must be taken with the patient recumbent, since fluid levels are confusing and contribute nothing to the diagnosis.

Many cases of acute gastroduodenal dilatation are cured by Wangensteen suction, and therefore the differential diagnosis between this syndrome and that of acute intestinal obstruction is not often made. The author's three aims in the treatment are: (1) emptying the stomach and keeping it empty, (2) relieving the obstruction of the duodenum, (3) replenishing the lost electrolytes and maintaining the nutrition or correcting the emaciation. Elevation of the foot of the bed is of value. In milder cases the assumption of the knee-chest position and the use of small, frequent feedings may benefit the patient to such a degree that in a few days he will be able to eat normally. Operative intervention with the performance of a duodenojejunostomy is rarely, if ever, indicated except in cases in which volvulus or congenital bands are present.

A patient who has had an acute arteriomesenteric duodenal obstruction should be observed after he has recovered, to determine whether a chronic duodenal ileus is still present.

HAROLD LAUFMAN, M.D.

Mendelsohn, E. A.: Hiatus Hernia of the Stomach as a Source of Gastrointestinal Bleeding. *Radiology*, 1946, 46: 502.

The differential diagnosis of bleeding lesions of the upper gastrointestinal tract must consider hiatus hernia of the stomach which manifests itself in hematemesis, melena, or microcytic anemia.

The hiatus hernia may or may not be combined with a congenitally short esophagus, the presence of which plays an important, but not an exclusive, part in the origin of this condition. Insufficiency of the muscular hiatus and of the surrounding connective tissue, acquired with advancing age, is considered the decisive etiologic factor. The positive pressure within the abdomen gradually forces segments of the stomach through the weakened hiatus into the thorax, where negative pressure exists.

Of the 16 cases of hiatus hernia of the stomach observed in 1,000 consecutive gastrointestinal examinations, the greater number of patients with true hiatus hernia were beyond 50 years of age. There were 8 females and 8 males. In a surprisingly large proportion of the cases (5 out of 16) the diaphragmatic hernia was complicated by other lesions in the gastrointestinal tract. Duodenal ulcers were found in 2 cases, primary adenocarcinoma of the ileum with intestinal obstruction in another, and the 2 remaining patients showed multiple diverticula in the colon. The combination of diaphragmatic hernia with diverticulosis of the colon is well explained by the fact that both conditions are due to senile insufficiency of muscular and connective tissue.

In 3 of the 11 patients in whom no other gastrointestinal lesion was present, the hiatus hernia was practically asymptomatic. In 5, different degrees of epigastric pain and other digestive symptoms were recorded, and sufficiently well explained by the presence of the herniated stomach. A small peptic ulcer was found in only 1 of these patients. There was satisfactory response to medical management in all patients in this group.

The cause of hiatus hernia is considered to be venous congestion in the herniated portion of the stomach, due to muscular compression of the diaphragm. The swollen and congested mucosal layer can easily be traumatized, with the production of superficial bleeding erosions or deeper ulcerations. Accompanying attacks of precordial pain suggesting an acute coronary occlusion, or more chronic anginal seizures, can well be attributed to the constriction of the herniated stomach by the diaphragm, combined with pressure upon the heart itself.

STEPHEN A. ZIEMAN, M.D.

Sandberg, I. R.: On the Treatment of Perforated Gastric and Duodenal Ulcer. *Acta. chir. scand.*, 1946, 93: 467.

The author recommends the following procedure as being the normal method of treatment of perforated gastric and duodenal ulcer: suture alone or, preferably, excision of the ulcer plus suture, covering with an omental flap, mopping of the abdomen, and

gastrostomy. The operation is easy to perform, gives a lower mortality than that occurring with resection, and a good late result may be expected in about 40 per cent of cases. The author believes that with the use of this procedure, a resection can be avoided in many cases. If patients are treated by suture alone, a regular medical-dietetic treatment should follow. However, many patients have symptoms that persist or recur after a period of quiescence, and the control of such symptoms is important, for a secondary resection may later be necessary.

The primary operation may be performed at a small hospital which is equipped for only simple surgical procedures; should resection later become necessary, the patient may be sent to another hospital for operation. The author states that in certain cases a primary resection is to be preferred, but that the indications ought to be clear. A long history of ulcer in which the patient has undergone one or more series of medical-dietetic treatment, a short interval between the occurrence of perforation and the operation, and a but little affected general condition in a rather young or middle-aged patient who does not present signs of some other contraindicating disease, are prerequisite conditions for consideration of a primary resection by an experienced stomach surgeon.

In the case of a duodenal ulcer or a gastric ulcer situated in the pyloric region, a Witzel's fistula, or (better) a duodenal tube should be established. A gastroenterostomy should not be considered because of the risk of development of a peptic ulcer in the jejunum. However, should a primary gastroenterostomy be indicated on account of a marked stenosis, it is believed that a resection ought to be performed, if possible at the same time, in young individuals. In patients over 50 years of age, in whom the risk of peptic jejunal ulcer is not so great, a gastroenterostomy alone is permissible. Local and intravenous administration of sulfathiazole is probably of value. Intravenous drip infusion, and the control of fluid and salt balance are important.

If the diagnosis of perforated ulcer is clinically certain or highly probable, operation should be undertaken immediately without a preceding x-ray examination. However, should x-ray examination be desirable for the purpose of differential diagnosis, and free gas is not visible on the general survey pictures, the examination should be supplemented by having the patient drink a small quantity of opaque medium; thus the diagnosis of perforation or non-perforation is made considerably surer without any risk to the patient.

BENJAMIN GOLDMAN, M.D.

Monti, L.: Perforated Gastric Ulcer in a Patient with Gastric Neurinoma (Ulcer perforata dello stomaco in portatore di neurinoma gastrico). *Arch. ital. chir.*, 1944, 66: 64.

A 50 year old man from the country district was admitted with physical findings of a pleural effusion on the right side. This patient had suffered for a long time from brief respiratory attacks, during one

of which, 3 years ago, he had vomited about a quart of blood. The present attack had begun with fever and general physical decline about a month previous to his hospital entrance. On the day of entry 20 c. c. of clear fluid were withdrawn from the right chest cavity; the condition improved rapidly and a week later no fluid could be demonstrated. About this time, however, the patient lost his appetite and became very weak, the stool became tarry and an extreme anemia was uncovered. Roentgen examination of the gastrointestinal tract failed to disclose anything abnormal, the stomach being covered and obscured by the residual shadow-producing medium in the distended colon. In the succeeding days the anemia improved under transfusions and hypodermic glucose solution; however, 3 weeks after entering the hospital the patient experienced a sudden lacerating pain in the epigastrium, radiating to the entire abdominal region and particularly to the back and right hypochondrium. The abdominal walls became retracted, the face pallid and anxious, and there were signs of physical collapse.

The diagnosis was given as perforated gastric ulcer, and the abdomen was opened under local anesthesia. A perforation was found into the lesser peritoneal cavity, through the posterior wall of the stomach near the lesser curvature. However, near the point of perforation was a nodular tumor the size of an adult fist. Drainage was instituted and the abdomen closed. The patient died that same night.

At autopsy extensive histological examination of a variety of tissues from the principal organs of the abdomen and chest failed to disclose any other changes than those ascribable to a catarrhal condition. The tumor itself exhibited the typical histological picture of a gastric neurinoma, with evidence of healed areas of ulcerative breakdown of the gastric mucosa, and the author believes that the ulceration which produced the perforation, although situated adjacent to the new growth and not involving the tumor mass itself, was nevertheless caused by pressure conditions arising from the rapid growth of the neoplasm. The pleural effusion also might have been due to irritation from the tumor which was adherent to the under surface of the diaphragm. No metastases could be demonstrated.

JOHN W. BRENNAN, M.D.

Illingworth, C. F. W., Scott, L. D. W., and Jamieson, R. A.: Progress after Perforated Peptic Ulcer. *Brit. M. J.*, 1946, 1: 787.

This is a survey of 880 patients treated for acute perforation of peptic ulcer in the Western Infirmary of Glasgow during the years from 1938 to 1943, with 733 (83%) survivals. Of the latter group, 666 could be traced and 596 came in for follow-up examination. Sixty-seven patients were untraced; 10 were traced but living abroad; 17 were traced but all of them refused to co-operate, which makes a total of 94 patients, or 12 per cent of the survivors who were not re-examined.

Ninety-five per cent of the patients were male. The ulcer was situated in the duodenum in 87 per cent of the cases. In all but 10 patients the operation was limited to simple closure of the perforation, and in the remainder a supplemental gastroenterostomy was added. On discharge from the hospital all of the patients were given instructions as to diet and therapy.

At the end of the first year, 60 per cent of the patients remained symptom free, about 20 per cent had had a relapse with mild symptoms, and the remaining 20 per cent had had a severe relapse. With the passage of time the percentage of relapses increased, so that by the end of the fifth year about 30 per cent remained symptom free, 20 per cent had had mild relapses, and 50 per cent had had severe relapses.

In general, the women seemed to fare better than the men, but the number of women was too small to allow any reliable conclusion. Older individuals fared better than younger ones. The influence of the duration of ulceration prior to perforation on subsequent health was interesting. The longer the ulcer had been present before perforation, the poorer the health in the postoperative years. It was surprising to find that there was no difference in the morbidity between the various social grades in this series. This disproves the common belief that the treatment of peptic ulcer has more satisfactory results in private than in hospital practice, and shows that the economic status of the patient does not alter the course.

SAMUEL J. FOGELSON, M.D.

Scott, O. B., and Brunschwig, A.: Submucosal Lipomas of the Stomach: A Review of the Literature and Report of a Case Associated with Carcinoma. *Arch. Surg.*, 1946, 51: 255

In the last decade there has been an increasing interest in the problems associated with benign tumors of the stomach, which have been considered as relatively rare. Although reports now indicate that they occur with greater frequency than previously supposed, a few of the types of benign tumors may still be considered rare, and, of these, one of the least rare is the submucosal lipoma.

Rumold, in a review of the literature from 1935 to 1940, was able to find 32 cases, to which he added one case of his own, bringing the total to 33. Since then several cases have been reported. The authors review briefly the recent cases and report a case of submucosal lipoma of the pylorus associated with an infiltrative adenocarcinoma.

The cause of the lipomas of the intestinal tract remains unknown. Some authors have suggested the possibility of congenital influences, since a familial pattern was noted by Rumold in his case of submucosal lipoma of the stomach in a patient who had a brother, a sister, and two nephews, all of whom had lipomas of the extremities. The sex incidence is apparently equal.

The lipomas of the stomach may be either subserosal or submucosal, and may be single or multiple. The submucosal types vary from a few millimeters

to several centimeters in diameter and may be sessile or pedunculated. Although their position is variable they often occur in the region of the pylorus and may produce obstructive symptoms. Overlying the tumor the mucosa is usually smooth, but ulceration is not uncommon. Schindler found that a fairly constant feature of submucosal tumors is the stretching of adjacent rugae so that they appear to bridge the space between the top of the tumor and the surrounding mucosa. Grossly and microscopically, these tumors have the characteristics of adipose tissue with some degree of lobulation.

The clinical picture is variable but not unlike that of other benign gastric tumors.

The preoperative diagnosis of benign gastric tumors can often be made by roentgenographic and gastroscopic examinations.

The treatment of submucosal lipomas of the stomach does not differ from that of other benign gastric tumors. Although local excision may suffice, Rumold emphasized that a portion of the involved gastric wall should be excised to avoid the possibility of recurrence.

The occurrence of both carcinoma and lipoma in the stomach, as in this case, is coincidental, as submucosal lipoma is to be regarded neither as a premalignant condition nor as evidence of carcinogenic factors in operation.

HARRY W. FINK, M.D.

Foile, P. S.: Intestinal Obstruction following Abdominal Battle Wounds. *N. England M. J.*, 1946, 234: 498.

Factors that predispose to the formation of adhesions are multiple bowel perforations and lacerations of the bowel, particularly when these have resulted in considerable peritoneal soiling, hemorrhage, blast, lacerations of the mesentery, delay prior to initial surgery, and infection. Since battle injuries may involve all these factors, it is not surprising that subsequent obstruction often results. The author warns of the constant danger that an enthusiastic surgeon will do too much in cases of this sort. The natural desire to free the bowel completely should be curbed, and attention confined to the few points at which some degree of definite obstruction has occurred.

A totally obstructed patient should be subjected to as little trauma as will accomplish the goal of the operation—namely, re-establishment of the intestinal stream. Once the obstruction has been relieved, functioning bowel, even though densely adherent, should be left alone. It is predicted that many cases of acute intestinal obstruction will be encountered for many years to come in veterans who have suffered abdominal wounds. Five typical cases are presented: one of the cases showed a tangled mass of adhesions involving practically the entire bowel with only the jejunum and the transverse and descending colon free. This case was the only mortality encountered in the series and demonstrated the extreme involvement that may occur.

Early signs and symptoms should receive careful evaluation and close watching. The author suggests

that interval lysis with the installation of amniotic fluid may be advisable when chronic symptoms suggest impending difficulty, but in the present series this form of treatment was not used.

HAROLD LAUFMAN, M.D.

Kautz, F. G., Lisa, J. R., and Kraft, E.: Congenital Duodenal Obstruction. Report of Cases and Review of the Literature. *Radiology*, 1946, 46: 334.

Congenital obstruction of the duodenum, first described by Calder in 1733, was long considered a fatal malformation of the newborn and a subject merely of academic interest. In view of the rapid downhill course within a week or two after birth, the diagnosis was formerly made by the pathologist at the autopsy table. More recently, however, the condition has been recognized clinically and roentgenologically, and during the past decade surgical procedures have been carried out successfully.

So far about 300 cases have been recorded in the literature. Approximately 50 patients have been operated upon, one-half of whom survived. Improved methods, introduced by Ladd, Donovan, and their coworkers, have reduced the mortality rate still further. In spite of these advances, however, the disorder has received but little attention in the roentgen literature.

Congenital obstruction of the duodenum in its complete form is incompatible with life. Since the

Fig. 1. Four types of congenital duodenal obstruction: 1. Diaphragm (arrows) with or without perforation, most frequent type. 2. Filiform lumen (arrow). 3. Blind ends connected by fibrous cord (arrow). 4. Blind ends without connection (arrows) (aplasia).

downhill course is rapid, survival depends on a correct roentgen diagnosis and an emergency operation within the first week of life. When the surgeon succeeds in establishing continuity of the intestine and in excluding coexistent malformations elsewhere, the prognosis is favorable.

The characteristic roentgen findings of atresia and subtotal stenosis are dilatation of the stomach and gross distention of the duodenum, sometimes with an hourglass appearance, complete 6-hour residue, and lack of intestinal pattern.

Four cases of atresia and 2 cases of subtotal stenosis are reported. The essential clinical and pathological features are discussed. The literature is reviewed.

JOHN E. KIRKPATRICK, M.D.

Hicken, N. F., Snow, S., Coray, O. B., and Jackson, E. G.: Complete Duodenal Obstruction in the Newborn. *Am. J. Surg.*, 1946, 71: 461.

Five cases of acute obstruction of the duodenum occurring in the newborn are presented. The factors causing complete duodenal obstruction in the newborn may be classified as those producing intrinsic occlusion and those producing extrinsic compression of the bowel lumen. The intrinsic occlusions represent a failure of the duodenum to form a patulous lumen. If the entire duodenum remains as a solid cord, the condition is complete congenital atresia. Occasionally a partial or segmental vacuolation occurs which causes a portion of the duodenum to be normal while other segments have no lumen. In rare instances the entire duodenum may be patulous except for a small transverse diaphragm which prevents the flow of duodenal fluids into the jejunum. The extrinsic obstructions are caused by external compression of a normally developed duodenum.

The cardinal symptom is vomiting, which begins shortly after the first feeding and becomes progressively worse until it assumes a pernicious nature. Because the occlusions generally lie below the ampulla of Vater, the vomitus is stained with bile, but the meconium is acholic. Should there be a complete atresia of the duodenum, or if the obstruction is situated at the level of the ampulla of Vater, neither the regurgitated food nor the stools contain biliary pigments. In suprapapillary obstructions the vomitus is acholic while the meconium is stained with bile. Whenever the obstructive agent interferes with the flow of bile into the duodenum, the infant becomes jaundiced. Distention is invariably present and is always limited to the epigastric area, while the lower abdomen remains flat, because the ingested air and gas do not pass into the small intestines and colon below the level of obstruction. Dehydration, electrolyte imbalance, inanition, and mild hyperthermic reactions develop rapidly.

Although clinical observations may suggest the diagnosis of acute intestinal obstruction, roentgenographic studies are necessary for accurate localization of the lesion. Simple films of the abdomen may demonstrate gaseous distention of the stomach and duodenum but fail to outline gas bubbles in the

lower intestines. If an enema has been given prior to x-ray examination, the accidental introduction of air into the colon may lead to an erroneous conclusion of a patent intestinal tract. If the gas bubbles do not change their position on changing the position of the patient, a fixed congenital deformity can be assumed. When contrast media are used for x-ray studies care must be exercised to prevent the aspiration of this material. The hazard can be minimized by injecting the barium mixtures through a small Levine tube and aspirating the mixture by gently lavaging the stomach at the conclusion of the study. Detection of a faulty rotation of the midgut can be made by employing a barium enema.

Thorough preoperative preparation with fluids, transfusions, vitamin administration, and constant decompression of the dilated stomach are essential. The primary objective of every operation is to relieve the obstruction in the quickest and safest manner possible. Many of the procedures which are applicable to adults cannot be used in infants because of the profound physiological disturbances which they produce. Reconstructive measures should aim to divert the essential digestive juices into those segments of the intestinal tract where they normally function. When confronted with complete atresia of the duodenum one must relieve the gastric obstruction and decompress the obstructed extrahepatic biliary radicals. This requires two separate procedures. The authors have employed both antecolic and posterior gastroenterostomies to relieve the duodenal stasis but advise the antecolic anastomosis if the infant is in a precarious state. The biliary stasis can best be corrected by performing a cholecystogastrostomy. The tip of the indwelling Levine tube is pulled through the newly formed stoma so that it lies within the lumen of the gall bladder and provides for biliary decompression. Nonrotation or incomplete rotation of the midgut may produce so much tension on the short superior mesenteric vessels that an acute obstructive angulation of the duodenum may be produced at its junction with the jejunum. In some instances, release of the adhesions may correct the kinking, but as a rule the vascular pedicle is so short that duodenojejunoanastomosis is necessary.

In this series of 5 cases there was an overall mortality of 80 per cent. In retrospect, the authors believe that an early diagnosis combined with corrective surgery might have saved 4 of the 5 patients. They emphasize the fact that the cicatricial bands which are compressing the duodenum may not be solely responsible for the obstruction. In 2 of their patients there was an associated segmental atresia of the duodenal lumen.

JOHN L. LINDQUIST, M.D.

Mehn, W. H., and Morrow, W. J.: Enterogenous Cyst of the Ileocecal Region. *J. Pediatr.*, St. Louis, 1946, 28: 605.

Enterogenous developmental cysts of the ileocecal region are infrequent. They may occur anywhere

from the base of the tongue to the rectum, but they are most commonly found in the region of the ileocecal valve.

Enteric cysts arise from and reproduce the structure of the normal intestinal wall. They are lined by intestinal mucosa and their walls contain varying amounts of fibrous tissue and smooth muscle. They may protrude into the bowel lumen or extend outside of the wall according to whether they grow submucosally or subserosally. Attachment to the mesenteric border is common. The cavities of the cyst are unconnected with the lumen of the bowel and contain mucus.

The authors report 1 case, that of a 14 day old male infant in whom the findings, although not entirely typical, warranted a preoperative diagnosis of acute intussusception. At operation an obstructing cyst was found in the lumen of the terminal ileum. This was resected with the adjacent bowel, and a primary anastomosis was made between the ileum and the ascending colon. Examination of the surgical specimen showed no communication between the mucus-filled cyst and the intestinal lumen. Microscopically, the cyst wall contained layers resembling those of the terminal ileum. The clinical, surgical, and pathological findings in this case are comparable to those described by previous authors.

JOSEPH GASTER, M.D.

De Pablo, J. S., and Trallero, S.: A Probable Case of Traumatic Appendicitis (Un probable caso de appendicitis traumática). *Actas Soc. ciruj.*, Madrid, 1945; 5: 33.

This article discusses the probability of traumatic appendicitis and reviews the medicolegal aspects of this condition. A case report in which every evidence pointed to trauma as the cause of the appendicitis is presented.

A 14 year old boy was struck in the abdomen while playing ball. The pain was so intense that it impeded his play. After a few minutes of respite, however, he continued the game. The pain recurred and he was in distress that night and the next day. A little later it became localized and intense in the lower right quadrant of his abdomen and was associated with nausea and vomiting.

His leucocyte count was 21,000 with 70 per cent segmental cells. At operation a retrocecal appendix was found, greatly swollen and edematous in its distal portion. Dense fibrous exudate was present. The appendix was removed and the postoperative course was uneventful. Gross examination of the appendix showed a gangrenous appearing organ with mucosa of a bluish color. There were no visible perforations and the mucosa and serosa were edematous and densely infiltrated. At the base was an olive pit.

The authors review the literature on the pathogenesis of traumatic appendicitis and query whether one traumatic stroke in the abdomen is capable of producing appendicitis, or whether a lesion is formed which permits the entrance of bacteria and infection.

The frequency and prognosis of such lesions are discussed.

STEPHEN A. ZIEMAN, M.D.

Keyes, E. L., and Cook, M. M.: The Diagnosis of Acute Appendicitis in the Presence of Diarrhea. *Arch. Surg.*, 1946, 52: 429.

The authors point out that the diagnosis of early appendicitis is difficult, especially in the presence of diarrhea, in which the picture might resemble that of acute enteritis. They stress the importance of a carefully taken history and point out several features which should help to differentiate the two diseases.

Table 1, below, summarizes the findings in the cases reported by the authors.

The authors call the phenomena listed in this table under points 1 to 4 "gas stoppage sensation" ("a patient is apt to feel that if he 'could pass gas' he might obtain relief from the 'continual gripe' or the 'tight feeling' . . .") and consider it as very characteristic for early acute appendicitis. One may expect positive answers to questions asked in reference to these points in 60 to 80 per cent of all patients with acute appendicitis. The gas stoppage sensation is absent in every patient with perforated peptic ulcer, renal disease, and gallstone colic. In acute cholecystitis it was always absent except in 1 patient; it was absent in acute salpingitis, except in 2 cases and in ruptured ectopic gestation, except in 2 cases; and it was absent in 150 cases of acute enteritis. It occurs constantly at the onset of acute small bowel obstruction, although in such cases vomiting rapidly comes to exceed the downward urge.

As to the time element, the authors show that pain in enteritis is intermittent, in spells lasting for minutes and disappearing for minutes, while pain in

TABLE 1.—DIFFERENTIAL DIAGNOSIS OF EARLY ACUTE APPENDICITIS AND ENTERITIS

Point	History	Acute appendicitis early stage	Enteritis
1	Pain	Persistent in midline despite defecation	Varying situation; intermittent; relieved by defecation completely, if temporarily
2	Bowel urge	Associated with pain; persists despite defecation	Associated with pain; relieved by defecation completely, if temporarily
3	Diarrhea	Uncommon; subordinate to bowel urge	May dominate clinical picture
4	Nausea	Subordinate to bowel urge; occurs subsequent to pain	May exceed bowel urge; may precede pain
5	Vomiting	Present in less than half the cases	Present in over half the cases
6	Tenderness	Physical Findings None in some cases; epigastric, periumbilical or rectal in others	None in some cases, variable in others; bowel sounds may be hyperactive
7	Fever	None or slight	Same
8	White blood cell count	Laboratory Findings Usually over 10,000	Lower average

appendicitis lasts for hours or days, and in recurrent appendicitis pain is continuous, occurring in distinct prolonged attacks.

When the process localizes in appendicitis the following table is applicable:

Point	History	Acute appendicitis, late stage	Enteritis
1	Pain	Shifts to right lower quadrant; may shift elsewhere; may fail to localize	Rarely shifts
2	Bowel urge	Usually disappears	Usually persists intermittently
3	Tenderness	Physical Findings In right lower quadrant, increasing toward McBurney's point, may be atypically situated, occasionally absent; rectal tenderness common	Usually less pronounced and more variable in situation; bowel sounds may be hyperactive
4	Spasm and rebound	Common; cough and rebound tenderness common	Rare
5	Fever	Normal to 102, occasionally higher	Lower or higher
6	White blood cell count	Laboratory Findings Average—15,000 to 25,000	Average 12,400

As to vomiting, the authors stress that it occurs less often in early acute appendicitis than is supposed for some authors, while it is quite frequent in acute enteritis.

This is a careful clinical study which might well be read in the original. **HEINRICH LAMM, M.D.**

Berk, J. E.: Carcinoma of the Colon and Rectum. Med. Clin. N. America, 1946, 30: 307.

Benign colonic neoplasms, such as adenomatous polyps, may undergo malignant transformation. The possibility of a potentially malignant state in the colon acting as a precursor to the development of carcinoma is an attractive hypothesis, but it remains to be proved that the changes noted are precursors and not effects of the cancer. Inflammatory lesions of the colon may predispose to the development of malignancy. The consensus is that the polypoid lesions of ulcerative colitis may become malignant, but probably do so rarely. Diverticulitis has long been thought to predispose to cancer. The important thing to bear in mind is that an individual with diverticulitis may also have a carcinoma.

Anal cancer may take origin in fistulas, inflamed fissures and anal tags, and other inflammatory lesions of the anus but this is an exceedingly rare occurrence. Chronic irritation of the colon, as from constipation and parasitic infestations, appears to play little or no rôle in the production of cancer. A predisposition toward colonic cancer may be an inherited susceptibility for the actual development of carcinoma.

About two-thirds of the malignant tumors of the large bowel involve the left colon and about one-

third, the right colon. The rectum, sigmoid flexure, cecum and ascending colon, transverse colon, descending colon, hepatic flexure, and splenic flexure tend to be involved in the given order with regard to frequency.

Adenocarcinomas of the large intestine may be divided into four main types:

1. **Nodular.** This type projects into the lumen as a globular sort of mass which frequently ulcerates.
2. **Scirrhous.** Intestinal obstruction is frequent in this type. It is rare in the rectum and is found more often in the left than in the right side of the colon.

3. **Colloid.** This type is found most commonly in the rectum and rectosigmoid and in the cecum and ascending colon.

4. **Papillary.** These tumors are not very common and tend to occur most often in the left colon.

Numerous schemes have been advanced to classify carcinomas of the large intestine as to their grade of malignancy. The various criteria used include: (1) the boundaries reached (Dukes); (2) the pace of growth determined by the percentage content of differentiated as compared with undifferentiated cells observed microscopically (Broders); (3) the degree of histological differentiation; and (4) the amount of mucin demonstrable in the cancer cell, on the presumption that the mucus formation is an expression of cell function.

The tendency to metastasize is generally greatest in the rectum and sigmoid and least in the cecum. Investigators have shown (1) that age apparently exerts no important influence; (2) that there is no correlation between the size of the lesion and the presence of metastasis, the incidence of metastasis being even higher in persons with smaller lesions than in those with larger ones; (3) that the higher the grade of malignancy the more likely the presence of nodule metastasis; and (4) that retrograde spread and interrupted spread may occur with normal nodes intervening between the primary site and the next nearest involved node.

The average age of patients with cancer of the colon or rectum is 55 years with 85 to 90 per cent of the cases occurring in persons older than 40 years.

The duration of symptoms before diagnosis is longer on the right side of the colon than on the left side of the colon. In the early stage any symptom sufficient to attract attention to the bowel may be a symptom of cancer. In patients with carcinoma of the right colon, constitutional symptoms are prominent and a tumor mass is often palpable while obstruction is not very common. Characteristically, no blood is grossly discernible in the stools. The symptoms that characterize carcinoma of the left colon are predominantly those of intestinal obstruction. The progressive character of the constipation is of the greatest importance. Visible blood loosely attached to the outside of the stool is observed by approximately one-fourth of the patients.

Carcinoma of the rectum is characterized in the main by a change in the character of the stool, alter-

terminal bowel as low as possible and yield more accurate information with regard to the position of the terminal bowel in cases of imperforate anus.

The cardinal points in the treatment of imperforate anus are: (1) there is no need to hurry, and patients need not be rushed into the operating room improperly prepared, simply because of evidences of distention; (2) finger pressure in the perineum toward the terminal bowel will reveal the distance to be covered; (3) a small incision should be made to permit the finger to bore its way to the bowel instead of laying the perineum wide open, thus opening a large raw area for secondary infection as well as destruction of the sphincter; (4) when the bowel is reached, sweep the finger around it to free it, grasp the lowest point with a clamp, and with gentle traction on this, gradually free it all around until it can be brought down as far as possible; (5) if the entire bowel can be brought to the skin surface, open it and suture it to the surrounding skin; if only part way, anchor it on the four quadrants to the surrounding muscles, open the end, free and bring the mucosa down and suture it to the skin; (6) because of the danger of skin contraction, these cases must be dilated weekly at least, until they are about 1 year old; (7) no anesthesia is required when operating through the perineum during the first week of life.

In some cases complete descent of the bowel will not occur until some 48 hours after birth, while in others it will not take place until the patients are four or five days old. Thus a waiting policy up to a certain limit is desirable. Even the appearance of meconium in the urine, indicative of fistula into the urinary tract, is not an indication for hasty action. The lack of intestinal flora at this age and the feeding of sterilized foods and liquids will delay the danger of ascending urinary infection.

The author stresses his belief that the great majority of these cases can be reached through the perineum without colostomy if they are permitted sufficient time to develop or distend their terminal bowel. However, one case is reported in which there was no rectum or anal canal in connection with the maldevelopment of the sacral bones and coccyx. The terminal end of the bowel was in the sigmoid region. Because this baby passed meconium in his urine, the author established a colostomy under local anesthesia. Another case was that of a 4-month old child who had never had a normal movement of solid or semisolid material. He was born with an imperforate anus, but when 3 days old, a small fistula developed near the base of the scrotum, through which liquid and gas were evacuated daily. Despite this defect, the child appeared well nourished. In another baby with an imperforate anus, a fistulous opening developed (after 48 hours of life) in the middle of the posterior surface of the scrotum, through which a small amount of meconium escaped. By the end of that day, the entire rectal ampulla was distended. By the following day a stricture in the sigmoid had dilated spontaneously and the rectum was well distended down almost to the perineum.

Operation was performed at 80 hours of age with an uneventful convalescence.

Daily dilations are required in most cases because of the tendency for the skin about the operative opening to contract. If distention reaches the frightening stage, the danger is in aspiration suffocation, and not in toxicity. This danger can be markedly avoided by keeping the baby on its ventral surface entirely.

HAROLD LAUFMAN, M.D.

Polsie, P. S.: Closure of Colostomies. *N. England J. M.*, 1946, 234: 464.

The closure of colostomies in 26 cases following battle injuries is reviewed. In most cases of injury to the large bowel, the injured site had been exteriorized, and most of the cases that presented any great amount of bowel damage had been subjected to a colostomy. Only in occasional cases did the record state that the limbs of the bowel had been sutured together to form a well defined spur. By digital examination, however, it was possible to decide which cases were suitable for crushing, and most of the cases were prepared for closure in this manner.

In 26 cases the colostomies were closed by applying clamps to reduce the septum between the bowel loops, and this was followed by simple transverse suture of the stoma, after the bowel had been freed to below the peritoneum, and the adjacent rim of skin with any protruding and edematous portion of the bowel had been resected. It was usually found that this section of the bowel was fairly well walled off from the general peritoneal cavity by intraperitoneal adhesions, and no attempt was made to free them. After closure the bowel was dropped into the abdominal cavity and the peritoneum was closed over it, but the adhesions were not completely freed in the general peritoneal cavity. The patients had extremely little postoperative reaction or distention. Such a procedure can be carried out through a small elliptical incision, a small margin of skin around the stoma being excised, even when it is situated well in the flank or close to the inguinal region. In only 2 cases were the loops resected and the free ends anastomosed.

A practical criterion as to the adequacy of the preparation is the patient's ability to resume normal bowel movements. Patients with evacuations which occurred exclusively through the abdominal stoma began to have normal defecations after some of the opposed bowel wall had been crushed. This function can be tested by plugging the stoma with a vaseline gauze pack and supporting it with a firm pressure dressing.

In some cases there is a question whether sufficient lumen has been left after closure of the bowel. This happens when the opening is particularly large so that its inversion with two layers of sutures may have encroached too much on the amount of lumen present. This is true especially when the absence of a well defined spur has made it advisable to do little or no crushing. In such cases a transverse closure is

Miller, D.: Papilloma of the Gall Bladder. *N. England J. M.*, 1946, 234: 473.

Three cases of papilloma of the gall bladder were observed by the author during the past few months. In each case the preoperative diagnosis was correctly made by roentgen studies of the organ. There appears to be no significant association of papillomas of the gall bladder and carcinoma of this structure. In a study of 1,700 gall bladders, Kirklín reported that 8.5 per cent were found to contain one or more papillomas.

Papillomas appear as projections from the mucous membrane of the gall bladder. The pedicle may be very thin or quite broad. The symptoms which bring the patient under observation are similar to those of chronic cholecystitis. The treatment is cholecystectomy.

The diagnosis can readily be made by roentgen ray examination. The best time for examination is the twentieth hour after ingestion of the dye. Stones usually change their position with succeeding examinations, are often bunched together, and are most frequently found at the fundus. Most papillomas are discrete, do not change position, and are rarely found at the fundus. Adenomas are larger than papillomas, measuring 2 cm. or more in diameter as against 0.5 to 1.0 cm., and are frequently present at the fundus. EARL O. LATIMER, M.D.

Mallet-Guy, P., JeanJean, R., and Feroldi, J.: The Syndrome of the Sphincter of Oddi (La maladie du sphincter d'Oddi). *Lyon chir.*, 1945, 40: 553.

For 20 years there has been periodic reference to the syndrome associated with spasm or stricture of the sphincter of Oddi and a parallel has been drawn between this and the familiar clinical picture of spasm or stricture of the sphincter at the bladder neck.

The contribution made in this article is the manometric study of the bile duct under conditions of sphincter spasm and the visualization of the lesion by means of radiopaque media. These studies were carried out at operation in 35 cases. Hypertonia was reported after cholecystectomy in 4 cases, in connection with a functionless gall bladder in 5 cases, following aseptic cholelithiasis in 3 cases, and in 5 cases of chronic cholecystitis without stones. Seven cases of essential hypertonicity of the sphincter of Oddi are described, 3 cases of generalized hypertonicity of the biliary passages, and 5 cases of hypertonicity of the sphincter with hypotonia of the gall bladder.

As far as the manometric studies were concerned, the following observations were made: the normal pressure in the common bile duct is about 12 cm. of water, but in the pathological cases under discussion the pressure was from 15 to 20 cm. of water in 10 cases, under 12 cm. in 2 cases, and over 20 cm. in 4 cases (25, 28, 30, and 40 cm. respectively). In the gall bladder, the pressure is regarded as normal at 18 cm. of water, or thereabouts, but in this syndrome the pressure was found to be between 20 and 40 in

12 cases, and below 18 (10 to 15) in 4 cases; in 2 cases the pressure was normal. The roentgenographic appearance of stricture is characterized by dilatation of the common duct and a tapering of the radiopaque material as it approaches the sphincter; in the essential hypertonicities the material ends at the sphincter and resembles a finger in a glove.

In 4 cases there was a chronic hypertonicity and sclerosis of the sphincter which was relieved by operation. Histological studies of an excised portion of the sphincter showed smooth muscle hypertrophy and sclerosis. The manometric studies are supported by pressure graphs of the condition found before and after operation and the roentgenographic data are supported by diagrams. There are 4 illustrations of histological studies. Surgically, stricture was relieved by transduodenal section of the circular sphincter without interference with the longitudinal sphincter. Good surgical results are reported.

ADRIEN VER BRUGHE, M.D.

Mallet-Guy, P., JeanJean, R., and Servetaz, P.: Distant Results in the Treatment of Chronic Pancreatitis by Unilateral Splanchicotomy (Résultats éloignés de la splanchicotomie unilatérale dans le traitement des pancréatites chroniques). *Lyon chir.*, 1945, 40: 293.

The first observation on the treatment of chronic pancreatitis after the failure of bile drainage, by splanchicotomy on the left side, was made to the Lyon Surgical Society in November, 1942. This article consists of the report of 9 further cases of a similar kind which responded favorably to the same type of surgical treatment. Detailed case reports are presented, with 2 biopsies of the pancreas and 1 postmortem specimen. In several cases the bile ducts were visualized at operation by roentgen rays after the injection of contrast media. In 9 of the 10 cases the results were excellent from 12 to 35 months after operation. There was 1 death 15 months after operation from pulmonary abscess and it was from this case that the autopsy specimen was obtained.

In all but 1 of the cases other operative procedures on the biliary tracts were first attempted, usually cholecystectomy, although on 3 occasions cholecystogastrostomy was done. In all cases the pancreas was edematous, nodular, hyperemic, and in some there were firm adhesions and fibrosis which would have made pancreatectomy a hazardous procedure. It appears that the body and tail of the pancreas were either more often affected or more affected than the head, with radiation of pain on the left side of the abdomen. In 1 case the head of the pancreas was most conspicuously involved with obstruction of the bile ducts; in this case a cholecystogastrostomy was done with resection of the right major and minor splanchic nerves. The pain on the left side was relieved by splanchicotomy on the left side in the other 9 cases.

Biliary hypertonicity is a complication likely to occur because of imbalance in innervation following splanchicotomy. This may be relieved, after

After laparotomy the fluid film between the liver and the diaphragm is broken, because the pneumoperitoneum is confined to the subphrenic spaces by the adoption of Fowler's position. This has two harmful effects:

1. The weight of the liver is now no longer evenly distributed on the undersurface of the diaphragm but falls on the suspensory ligaments of the liver. That this is a pain-producing event can be confirmed by observing any patient with a recently induced therapeutic pneumoperitoneum who is allowed to sit up, and it is possible that the abnormal stimulus induces a reflex inhibition of respiratory movements (particularly diaphragmatic), and diminution of the vital capacity. It is significant that operative diaphragmatic excursions are found to be slightly greater in extent in recumbency than in the erect position.

2. The abdominal muscles are the normal antagonists of the diaphragm. During expiration their contraction raises the intra-abdominal pressure, and the liver and the diaphragm are pushed, like a piston, into the lower chest. This mechanism is disturbed by the presence of an air-containing space between the diaphragm and the liver. From the purely mechanical point of view, one would expect the post-operative abdominal patient to breathe less efficiently in Fowler's position than lying on his back. In the latter position the air bubble passes anteriorly, and owing to the forward slope of the lumbar spine the

liver falls back into its normal relationship to the diaphragm.

The familiar picture of posterior basal hypostatic pneumonia is likely to become less common if freer movements ensure that all parts of the lungs have their turn to lie uppermost.

Fowler's position, maintained by a pillow behind the knees on which the calves rest, or by the soles of the feet pressing into the mattress, moreover, is particularly likely to induce thrombosis of the vessels in these areas.

The conflicting claims of recumbency and Fowler's position in shocked patients, and in those recovering from anesthesia, sometimes leads to their being propped up while still in a semi-paralytic or shocked condition, and being retained in position by the repeated efforts of the nursing staff and the judicious insertion of pillows at strategic points. This may prove calamitous to an overtaxed vasomotor system or may easily lead to fatal inhalation of secretions from the mouth or of vomit.

No one who has the most superficial acquaintance with nursing will dispute the difficulties entailed to the patient and nurses by the maintenance of Fowler's position, particularly if the patient is very ill. He must make a considerable muscular effort to maintain the position, and if this is not forthcoming he slips down and has to be replaced repeatedly. In either case rest and tranquillity of mind are lost.

STEPHEN A. ZIEMAN, M.D.

biliary manometric studies, by sphincterotomy at the sphincter of Oddi. Mild biliary hypertonia may be relieved by drainage of the duodenum or the use of atropine. The distribution of the 2 splanchnic nerves to the pancreas is not understood, but bilateral splanchnicotomy is not advocated because of possible deleterious effects on the blood pressure. Apparently the splanchnicotomy not only relieves the pain but also the chronic pancreatitis.

ADRIEN VER BRUGGHEM, M.D.

MISCELLANEOUS

Spalding, J. E.: Fowler's Position. *Lancet*, Lond., 1946, i: 643.

Spalding believes there is ample evidence to justify the abandonment of Fowler's position. The use of Fowler's position is based on the naive assumption that fluids always flow downhill. Recent criticisms of the position (mostly of an indirect nature) are concerned with its harmful side effects rather than with the central thesis of the prevention of subphrenic abscess.

The right subhepatic (Rutherford Morrison's) space should not be confused with the suprahepatic spaces. The suprahepatic spaces differ from the main peritoneal cavity in respect to the special function of the diaphragmatic lymphatics in the absorption of particulate matter from the peritoneal cavity, and in the pressure changes within the spaces during respiration, whereas the right subhepatic space belongs anatomically and physiologically to the abdominal cavity proper, and its frequent involvement in suppurative is merely the result of its anatomical relationship to the gall bladder, duodenum, and paracolic appendix.

The main route for the removal of particulate matter from the peritoneal cavity is by way of the diaphragmatic peritoneum. There is normally a steady upward flow of intraperitoneal fluid toward and into the subphrenic spaces, where it is absorbed and passes into the diaphragmatic lymphatics.

This upward flow is determined by the differences of pressure between the general peritoneal cavity and the subphrenic spaces. The pressures in the subphrenic spaces vary with the intrapleural pressures and not with the intra-abdominal pressure. Since the intrapleural pressure is negative and the intra-abdominal pressure is above atmospheric, the intraperitoneal fluid is sucked into the subphrenic spaces and is there absorbed by the diaphragmatic lymphatics. This is a *vis a fronte* mechanism applied to the thin film of fluid from the upper end, and the upward movement of such a film obeys the laws of capillary attraction rather than those of gravity. Large effusions will be influenced by gravity to a greater extent, but a proportion of their content is bound to enter the subphrenic spaces, whatever the position of the patient.

This upward flow of intraperitoneal fluid will be arrested if the continuity of the fluid is interrupted. This takes place in pneumoperitoneum if the patient

sits up and the air passes into the subphrenic spaces. Pneumoperitoneum is always present after laparotomy and in perforated ulcer, the two conditions which are responsible for the majority of subphrenic abscesses. Clearly another mechanism is involved.

When a patient with pneumoperitoneum sits up, the air collects in the subphrenic spaces under a pressure which is considerably less than the general intra-abdominal pressure, and undergoes a respiratory fluctuation. If he has at the same time a collection of fluid in the subhepatic region, this will tend to be aspirated past the liver into the subphrenic spaces. It may be objected that if the patient is sitting up there will be no fluid in the subhepatic region, because it will drain into the pelvis. That this is not so can be demonstrated on most patients with perforated duodenal ulcer. On opening the abdomen in such a case, the right subhepatic space is commonly found to be filled with fluid. If the operating table is now tilted into Fowler's position, it will be found that there is little or no leakage of the fluid out of the space. In fact, the right subhepatic space remains closed until the volume of the extravasated fluid exceeds its capacity, and only then does the excess fluid drain away along the paracolic gutter.

This upward movement of intraperitoneal fluid can be demonstrated radiologically in over a quarter of all patients with perforated peptic ulcer, if they are radiographed standing up.

Excluding peptic ulcers, direct infection of the subphrenic spaces from abscesses of the liver or spleen, or descending from the thorax, results from postoperative peritonitis or leaking peptic ulcer. The one factor common in these conditions is the presence of a pneumoperitoneum; and the practice of confining this to the subphrenic spaces by the adoption of Fowler's position facilitates the aspiration of infective fluid from the subhepatic region into the suprahepatic spaces. If the patient lies on his back, the air bubble is situated anteriorly against the abdominal wall, and the liver falls back into its normal relationship to the diaphragm. Even if the bubble is sufficiently large for its upper part to lie anterior to the liver, the subphrenic pneumoperitoneum is now in continuity with the general abdominal pneumoperitoneum across the anterior surface of the liver, and pressure differences caused by the respiratory movements merely cause a shifting of the bubble and not of fluid exudates.

It must be assumed that the normal mechanism has a definite protective value, and that the thin film of fluid enters the spaces at such a rate that the lymphatics are able to cope successfully with it. Moreover, large infected particles such as fecoliths and lumps of infected lymph are probably too large and to be propelled upward by the capillary force. On the other hand, the pressure differences occasioned by the pneumoperitoneum probably lead to the aspiration of fluid in bulk, with contained particles of microscopic size, with the result that the local defenses are overwhelmed.

The results in this small number of cases do not permit definitive conclusions, but they suggest that the effects of radium are greater when the circulation to the uterus is increased by a block of the lumbar sympathetic chain. This procedure is also helpful in that the uterine pain is relieved.

HARRY W. FINE, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Heller, E. L., and Fallin, W.: Ovarian Involvement in Hodgkin's Disease. *Arch. Path., Chic.*, 1946, 41: 282.

The authors state that the infrequency of ovarian involvement in the course of Hodgkin's disease is apparent from a brief perusal of the voluminous literature of this disease. No mention of such occurrence was noted in any of several standard textbooks of general surgical and gynecologic pathology. In numerous reports of unusual ovarian tumors no instance of Hodgkin's disease was encountered. However, a closely related lesion was reported in the first 50 cases filed with the Ovarian Tumor Registry of the American Gynecological Society. A 16 year old patient had lymphosarcoma of the ovary, secondary to intestinal lymphosarcoma. A photomicrograph revealed an infiltration strikingly similar in its general characteristics to that found in cases observed by the authors. Reviews dealing with Hodgkin's disease and reports representing relatively large series of cases, as a rule, do not refer to the ovary. It is noted that other reports of autopsy observations of 112 cases of Hodgkin's disease mentioned involvement of the ovary in 2 cases. In 1 case the involvement was microscopic in character; in the other the extent of involvement was not indicated. In a report based on a study of 57 cases of Hodgkin's disease of the female it was theorized that ovarian hypofunction might have been responsible for the occurrence of the disease in women; however, no lesions of the ovary were described to substantiate this concept, which was based chiefly on the history of reduced or suppressed menstruation in several cases.

That the infiltration of the ovary in Hodgkin's disease can be of considerable extent was illustrated in 2 cases studied by the authors. In each case the lesion of the ovary was misinterpreted as a primary tumor from its gross appearance. In 1 case, the resident physician who did the autopsy submitted a gross anatomic diagnosis of carcinoma, probably primary in the ovary, with widespread secondary involvement of the abdominal lymph nodes. In the second, the surgeon, an experienced gynecologist, noted during abdominal exploration an ovarian tumor of such size that it was considered primary in that organ, while the neoplastic enlargement of the mesenteric lymph nodes was considered to be secondary to the ovarian lesion.

A discussion of the diagnosis of Hodgkin's disease in these 2 cases is presented. In the first, the lesions of Hodgkin's disease were of two types. Throughout

the abdominal lymph nodes, which were regarded as the primary site, the picture was that of Hodgkin's sarcoma, with large irregular reticuloendothelial cells spreading diffusely throughout the interstitial pulp and sinusoidal spaces and exhibiting numerous mitotic figures. Pleomorphism was particularly pronounced. The second type was that designated as Hodgkin's paraganuloma with closely spaced lymphocytic cells of mature type, containing few of the larger reticuloendothelial cells which characterize Hodgkin's disease. Both types formed the ovarian tumor. Exception may be taken to the diagnosis of Hodgkin's disease in this case inasmuch as the characteristic granulomatous reaction was not observed. Acceptance or rejection of the diagnosis depends entirely on one's opinion as to the necessary diagnostic criteria. If one accepts the broader concept of Hodgkin's disease as one with a variable pattern, subject to mutations and transitions, in which the tumor changes into the sarcomatous and almost pure lymphoid variants, which have been repeatedly described, the diagnosis in this case becomes tenable. Attention is directed to a study recently published which illustrates such variability of the histologic pattern in Hodgkin's disease.

In the second case the ovarian infiltration was obviously lymphoid in character and not consistent with the pattern of any tumor primary in that organ. The occurrence of the larger cells of reticuloendothelial type, resembling poorly developed Sternberg-Reed cells, the scattered eosinophils, and the fibrosis led to the diagnosis of lymphoblastoma, probably Hodgkin's disease. The reaction subsequently noted in the lymph node from the arm appeared to substantiate fully the original diagnosis.

That the ovarian involvement in both cases was not the result of fusion with, and direct extension from, contiguous lymph nodes was manifested by the fact that the organs were freely movable, in normal position, and unattached to the neighboring nodes, and each was surrounded by an intact ovarian capsule.

The identification of sarcomatous cells within the lumens of veins within the substance of the ovary in the first case probably serves to explain the genesis of the infiltration in this organ.

In conclusion, the authors note that in 2 cases of Hodgkin's disease with unusual involvement of the ovary the gross appearance of the lesion was such that it was misinterpreted as a primary ovarian neoplasm.

HERBERT F. THURSTON, M.D.

Rhoads, E. E.: Granulosa Cell Tumor of the Ovary. *Am. J. Obst.*, 1946, 51: 560.

A brief review of the literature is presented, with a summary of 5 cases of granulosa cell tumor. The 5 cases are summarized because of the finding of granulosa cell tumor associated with premature menopause (amenorrhea with resumption of menstruation).

All patients were operated upon. Diagnosis was made after operation on gross examination and by

GYNECOLOGY

UTERUS

Traino Rao, G., and Pesce, V. S.: Carcinoma of the Cervix in Relation to Age, with Particular Reference to Young Women (Il carcinoma del collo uterino in rapporto alla età, con particolare riferimento alle donne giovani). *Clin. oncol.*, 1945, 47: 165.

In a previous article the authors made an analysis of cases of cervical carcinoma treated at the Clinica di Bari from 1936 to 1943, and in this article they give their conclusions pertaining to these studies. They are as follows:

1. The number of extremely young women affected has not increased in recent years.

2. The majority of authors differentiate the carcinoma appearing in the very young as being of a particularly malignant character, but the present authors recognize no basis for this teaching.

3. In the authors' series of cases a positive family history was found more frequently in subjects attacked in early life.

4. No correlation was noted between the physical habitus and precociousness of the onset of the disease.

5. The authors' results do not indicate that pregnancy in the younger age groups acts as a contributing factor in the incidence of carcinoma of the cervix. On the contrary, among the women who had had pregnancies, cancer was apt to appear with particular promptness after parturition.

6. No correlation was found between associated disease of the genitalia or other organs and the age of the patient.

7. The time intervals elapsing between the appearance of symptoms and the admission to the clinic were found to be approximately equal in all decades.

8. Although certain characteristics of anaplasia were present more frequently in the histological picture of the younger groups, these characteristics bore no definite relationship to the clinical course, and the degree of dedifferentiation was no more marked on the whole in the youthful than in the aged.

9. Carcinoma limited to the cervix was found most frequently between the ages of 40 and 50. It might be assumed from this that the disease spreads more rapidly in women of this decade. This assumption is offset by the fact that if this group is considered together with those patients in whom the disease had invaded either the parametrium or the superior portion of the vagina, no difference could be found in the percentage of frequency up to 50 years.

10. The results of treatment of carcinoma in patients under 30 years of age were no worse than those in patients in the decades over 30. On the contrary, the percentage of survivals under 30 was higher than in the older groups or than in the entire series. In the present series results from irradiation

alone were no worse in the youthful than in the older groups. EMM B. FARNSWORTH, M.D.

Perelra, A. De Sousa: A Basis for Sympathectomy for Cancer of the Cervix Uteri. *Arch Surg*, 1944, 52: 260.

In recent years several attempts have been made to relieve pain in certain cancerous diseases through action on the sympathetic nervous system. By blocking the sympathetic pathways with an anesthetic solution or by surgical interruption, the fibers conducting painful sensations arising in the area involved in the neoplasia are interrupted and the painful stimulations originating in the tumoral area cannot reach the cerebrospinal centers. In this way the visceral pain of tumors located in such organs as the uterus, stomach, pancreas and breast, can be relieved.

The investigations of others suggested that the radiosensitivity of a cancer may be favorably influenced by increasing the blood supply in the tumor during the period of irradiation. This led to investigation in carcinoma of the cervix uteri to determine whether the interruption of the sympathetic innervation by anesthetic block or by sympathectomy would, in addition to reducing the pain, also increase the blood supply to that region and be useful in the irradiation of the growth. Both experimental and clinical data are presented.

The interruption of the extrinsic sympathetic innervation of the uterus at the level of the lumbar sympathetic chain (first, second, and third lumbar ganglions) and of the roots of the hypogastric plexus, besides reducing uterine pain through the physiological block of the afferent painful pathways, also caused hyperemia of the uterus by blocking the efferent vasomotor sympathetic pathways of this organ.

In different types of abdominopelvic sympathectomies in dogs, such as resection of the presacral nerve, lumbar sympathectomy, and periaortic sympathectomy, an increased arterial circulation in the organs of the pelvic cavity resulted. The higher the abdominopelvic sympathectomy the greater was this increase in the collateral circulation. In the cases of lumbar sympathectomy, an increase of the arterial circulation was also observed in the lower extremity on the same side.

In the treatment of basal cell carcinomas and adenocarcinomas of the cervix uteri, the application of radium with hyperemia of the uterus obtained by repeated lumbar anesthetic blocks induced by procaine hydrochloride, in the first, second, and third lumbar ganglions, showed that the immediate results, in observation up to a year and a half, produced a greater percentage of healing (60 per cent) of the cancerous lesions in the cervix uteri than radium alone with 47 per cent healing. The total series included 62 cases.

with vaginal plastic surgery. It should never be used as a substitute for the standard vaginal plastic procedures in use for the same purpose.

EDWARD L. CORNELL, M.D.

Ortmayer, M., Koester, L., and Stetler, P. M.: Prolapsus of a Ureterocele through the Urethra. *J. Urol.*, Balt., 1946, 55: 515.

The rarity of prolapsus of a large ureterocele through the urethra warrants the report of such a case. Only 37 instances are found in the available literature.

The case report is that of a woman of 64 years. She had noticed urinary frequency for 2 or 3 months, together with dysuria and nocturia. Recently she had noticed hematuria and incontinence. Coincidentally with the latter, she felt something protrude from the vagina on straining, which receded during sleep or on being pushed back.

On hospital admission the patient had a mild fever which subsided after a few days. Catheterized urine disclosed innumerable leucocytes in clumps, and from 10 to 12 red blood cells per high power field. A culture yielded the bacillus coli.

On cystoscopy the right half of the trigone and region of the right ureteral orifice were obscured by a large sausage shaped tumor never seen in its entirety in one cystoscopic view. It was estimated to be from thumb to walnut size, and was covered by reddish puckered mucosa. It was somewhat velvety in its right half with fibrin adherent to its tip. The tumor could be pushed from right to left, but lay toward the right bladder wall. Its base took origin just inside the internal bladder sphincter and seemed to be quite broad, occupying one-half of the trigone. The right ureteral orifice could not be located on it or in the bladder.

On external examination at the time of prolapsus, a tumor approximately 2 by 3 cm. occupied the

urethral orifice and obscured the vaginal introitus. The left half of the tumor was deep red and the right half, salmon pink. It was soft throughout. Fine, minute strands of fibrin were adherent to its tip. A dimple near the tip on its top side suggested an orifice and easily admitted a probe to 4 cm. and a No. 6 F catheter to 35 cm. without obstruction.

The cystic mass was excised and electrocoagulated with uneventful convalescence and relief from the symptoms.

Three figures are presented in the original article; they show the typical excretory urogram, a reconstructed view when the ureterocele lay within the bladder, and a colored drawing of the ureterocele when prolapsed through the urethra. A few references to the literature are added.

T. FLOYD BELL, M.D.

Couri, A. A., and Ramos, A. V.: Urogenital Endometriosis (Endometriose uro-genital). *An. brasil gin.*, 1946, 11: 27.

The authors report a case of genital endometriosis in a 35 year old woman. The condition had spread from the genital organs to the urinary tract. Suspension of the uterus and bilateral salpingectomy did not relieve the symptoms consisting of colicky pains in the hypogastrium, dysmenorrhea, and dysuria. The gynecological examination revealed an enlarged uterus and a hard nodule on its anterior aspect. The cystoscopic examination disclosed the presence of 3 elevations in the trigonum.

A subtotal hysterectomy with preservation of the ovaries was performed and the patient made an uneventful recovery. She was given a series of x-ray treatments. Cystoscopic examination performed after the operation disclosed a cicatrization of the lesions. The histological examination established the diagnosis of endometriosis.

JOSEPH K. NARAT, M.D.

histologic means, but in some cases only after microscopic examination.

Of the total of 21 cases appearing on the record, only 2 were diagnosed as granulosa cell carcinoma. Granulosa cell tumors were catalogued according to age groups, namely: (1) prepubescent or childhood, (2) adult (those within the range of normal menstruation), and (3) postmenopausal. All 21 of the cases were in the second or third groups.

One patient menstruated twice after removal of a granulosa cell tumor, and at the present time is approximately 3 months pregnant. Follow-up studies showed that all patients were living and had no evidence of recurrence.

EDWARD L. CORNELL, M.D.

DeRoux, A. G.: A Contribution to the Study of Wilms' Tumor. (Contribución al estudio del tumor de Wilms). *Arch. cubanos cancerol.*, 1945, 4: 370.

The author reports 7 cases of Wilms' tumor found in Cuba. The most constant histological features of this tumor are: (1) the epithelial tubules of glandular aspect with hyperchromatic compact masses of pseudoglomeruli; and (2) the known fibroblastic malignant tumoral aspect. He found striated muscle in 70 per cent, smooth muscle in 28 per cent, cartilage in 28 per cent, and bone in 14 per cent of his cases.

The author discusses the general characteristics of this tumor, its clinical and pathological aspects and the pathogenic theories of its production.

WILLIAM E. RICKETTS, M.D.

Kleitsman, R.: The Robert Meyers Dysgerminoma Ovarii (Zur Frage des Dysgerminoma ovarii Robert Meyer). *Acta obst. gyn. scand.*, 1946, 26: 85.

The classification of certain tumors of the ovary according to their morphologic or histogenetic characteristics only, presents insurmountable difficulties. We owe it to the work of Robert Meyer that we are able to differentiate certain tumors by their functional and incretory effects rather than by their histological structure. This holds true especially for the differential diagnosis of dysgerminoma, arrhenoblastoma, and the granulosa cell tumors.

In contradistinction to the latter two, which may exert hormonal influence (masculinization or feminization), the dysgerminoma seems to originate from embryonal cells of the ovary which have not undergone sexual differentiation, and therefore the tumor does not have any hormonal influence.

This theory is further enhanced by the fact that we frequently find the tumor in persons with pseudohermaphroditic traits, and that it occurs especially in underdeveloped gonads of both sexes. Histologically, we find undifferentiated, large, polymorphic tumor cells. The stroma frequently reveals lymphocytic infiltration, and sometimes epithelioid and giant cells of the Langhans type are found in the stroma. The tumor usually grows rapidly and may infiltrate the mesovarium, uterus, and broad ligaments. Metastases are spread more frequently by the lymph than

by the blood circulation. The retroperitoneal lymph nodes are usually involved at an early stage.

The author discusses 3 cases which were observed at the Gynecological Hospital, Stockholm. One patient could not be operated upon radically because of metastases and was given postoperative radiation; she died 2 years after an operation on the metastases. The second patient, from whom both ovaries were removed, was not given radiation therapy; she is still in good condition after 6 years. The third patient, from whom a dysgerminoma on the right side, twice the size of a man's head, was removed, has undergone three pregnancies and is healthy 5 years after the operation.

MISCELLANEOUS

Aldridge, A. H.: An Evaluation of Methods for the Treatment of Urinary Incontinence. *Am. J. Obst.*, 1946, 51: 299.

Urinary incontinence may be due to fistulous communications between the urethra, bladder, or ureters and the vagina or uterus. However, the most frequent cause for loss of urinary control is incompetence of the urethral sphincter mechanism which controls urination.

Of the series of 118 urinary fistulas that has been reported, approximately one-third were caused by obstetric trauma, about one-half by surgical trauma, and 15 per cent by malignant neoplasms of the uterus, alone or in combination with irradiation used in treating such tumors.

Success in the treatment of a urinary fistula will depend upon careful preparation of the patient for operation (elimination of urinary infection, inflammation of the adjoining tissues, and anemia), accurate localization of the fistula, and the selection of a technique best suited to conditions found before and at the time of operation.

Repair of a fistula by a technique which depends upon denudation of its margins should never be attempted unless closure can be accomplished without undue tension on the surrounding tissues.

Flaps developed for closure of a fistula should be made up of the entire thickness of the vaginal wall to insure an optimum nerve and blood supply. The importance of closing a fistula on the first attempt is obvious. Every surgical failure decreases the chance for ultimate success.

Vaginal plastic procedures are successful in curing from 80 to 90 per cent of the patients who have urinary incontinence due to relaxation or partial destruction of the urethral sphincter muscles.

If function of the urethral sphincter muscles cannot be restored by vaginal plastic procedures, an attempt to establish urinary control by transplantation of adjacent muscles and fascia should be considered. A technique for this purpose recently described has been successful in 9 of 10 cases operated upon by 3 gynecologists.

As a means of relieving urinary stress incontinence, transplantation of fascia should always be combined

cause of the hydremia factor, or they may even give a false clue to diagnosis. Sternal marrow biopsy then becomes mandatory.

The normal erythroid marrow findings noted in healthy patients during pregnancy are conclusive in revealing that the lowered peripheral blood levels are due only to a hydremia, and speak for normal findings during pregnancy associated with blood dilution.

The characteristic marrow pattern noted in the various blood dyscrasias is of diagnostic, prognostic, and therapeutic importance in the management of both the hematological and obstetric problems.

One of the greatest values of sternal marrow biopsy is its negative value. The finding of a normal type of bone marrow definitely rules out the presence of a primary blood disease. The only exception is in cases of aleucemic lymphadenosis. (Lymph node biopsy will be needed.)

Costa, N. P., Chavanne, F. C., and Fernández, O. Z.: Hodgkin's Disease and Pregnancy (*Enfermedad de Hodgkin y embarazo*). *An. Ateneo Inst. maternidad*, 1945, p. 127.

This article discusses 5 cases in which pregnancy was complicated by Hodgkin's disease. The patients were subjected to radiation therapy which apparently had no ill effects on the fetus.

The patient who prompted a review of the 5 cases was a primigravida, 23 years old, who developed a swelling in her neck during the first month of pregnancy. The swelling gradually increased in size until it surrounded the entire neck. A biopsy was performed and the diagnosis of Hodgkin's disease was made. Radiation treatment was given which reduced the swelling perceptibly.

The 4 other cases of Hodgkin's disease were briefly reviewed, and it was concluded that radiation treatment was a valuable aid to the pregnant patient with Hodgkin's disease. STEPHEN A. ZIEMAN, M.D.

LABOR AND ITS COMPLICATIONS

Chimienti, P.: Cesarean Section for Epilepsy in Pregnancy (*Cesarea por estado de mal epiléptico en el embarazo*). *An. Ateneo Inst. maternidad*, 1945, p. 159.

The author discusses in detail the clinical course of a woman who suffered epileptic attacks several days prior to the onset of labor. After 7 hours of trial labor with no dilatation of the cervix and no advancement, the baby being alive, cesarean section was resorted to with surprising success. The postoperative course was complicated, however, with two new convulsive seizures. The therapeutic management consisted in saline and dextrose infusions. The patient recovered promptly and suffered no further attacks.

In discussing epilepsy, Chimienti describes the symptomatology and the differentiation between true epilepsy and hysteria. He divided the symp-

tomatology of true epilepsy into the aura period, the convulsive period, and the postepileptic state.

The article is concluded with briefs of some 43 case histories of pregnancy complicated by true epilepsy. The epilepsy in no perceptible way altered the course of the pregnancy, although a grave prognosis is given both for the mother and child.

Speiser, M. D., and Speck, G.: An Evaluation of the Treatment of the Persistently Unengaged Vertex in the Multipara. *Am. J. Obst.*, 1946, 51: 607.

Although this series is not large, it presents significant facts which must not be overlooked; namely, a corrected fetal mortality of 38 per cent and a maternal mortality of 0.5 per cent. Careful scrutiny reveals the fact that version and breech extraction per se cannot be condemned, because in 9, or 42.9 per cent, of the cases in which no other complications existed, satisfactory results were obtained. There is a tendency, however, to perform version and breech extraction without a thorough investigation of the causes for the persistent lack of engagement, which factors may be contraindications for this procedure.

In this series, it was found that among the 12 cases with disastrous results, 6 patients had cephalopelvic disproportion. Delivery by version and breech extraction was accomplished with difficulty and resulted in stillbirths with definite evidences of birth injuries. Unfortunately, an accurate appraisal of the size of the baby by clinical means is not always easy, especially in a multipara with an obese, pendulous abdominal wall. In addition, one usually seems less concerned in this type of patient after obtaining a history of spontaneous deliveries of moderately large babies. However, in those instances in which successive pregnancies are associated with progressively larger babies, the point may finally be reached when a baby may be too large to come through a pelvis which was adequate for previous infants.

During the 10 year period from 1933 to 1943 there were 22 cesarean sections performed after the onset of labor on multiparous patients in whom there was persistent lack of engagement of the vertex and in whom there were cephalopelvic birth injuries (intracranial hemorrhage and tear of the falx cerebri) after a 9 1/4 hours' labor with ruptured membranes for 5 1/2 hours. There were no maternal deaths in this group.

The failure to recognize cephalopelvic disproportion accounted for 50 per cent of the fetal deaths. In the presence of failure of engagement in the multipara, therefore, version and breech extraction should not be performed unless there is absolute proof that no disproportion exists.

The presence of a residual rim of the cervix may be a very definite hazard in the performance of a version and breech extraction. Version may be safely executed but the breech extraction must be deferred until the cervix offers no obstruction.

Upon recognition of cephalopelvic disproportion, cesarean section is the procedure of choice.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Virgili, G.: Clinicostatistical Considerations Based on 128 Cases of Extrauterine Pregnancy (Considerazioni clinico-statistiche su 128 casi di gravidanza extrauterina). *Riv. ital. ginec.*, 1943, 26: 400.

During the 6 years from 1936 to 1942, 128 cases of extrauterine pregnancy came to operation. This represented 3.05 per cent of the total admissions to the gynecological department, and 3.72 per cent of the patients coming to operation. In this period there was very little seasonal or yearly variation. The age period from 28 to 30 years showed the greatest incidence of this condition, the graph falling sharply away from this culmination toward the two extremes of the sexual period of woman. Forty-two and twelve hundredths per cent of this material consisted of nulliparous women, and 57.88 per cent of pluriparous; of the latter 48.6 per cent had had one previous pregnancy, 20 per cent had had 2 pregnancies, and 17 per cent had had 3.

Ancillary signs of pregnancy, such as vomiting, amenorrhea, enlargement of the uterus, softening of the cervix, are either insignificant or at least not as constant and characteristic in extrauterine pregnancy as in normal pregnancy; however, when evidence of extrauterine pregnancy is present, such matters become of import—even a delay of 1 or 2 days in the appearance of bleeding beyond the presumptive menstrual period assumes significance. Pain is a constant symptom of extrauterine pregnancy; however, the sign may be intermittent, or absent for weeks at a time, and even if present it must be evaluated properly with reference to other symptoms. A rise of temperature to 38° C. is not uncommon and should not divert attention from the possible presence of extrauterine pregnancy. If doubt still persists there is not much harm to be anticipated from a uterosalpingography or aspiration of a hematoma within the abdomen.

At operation on these cases signs of a previous pelvic infectious process were found in 1 of 3 patients. In occasional patients other pathological conditions such as ovarian cysts and uterine fibroids were also encountered, all presumably capable of causing the extrauterine abnormality but not necessarily doing so. However, once the extrauterine pregnancy is recognized, the only procedure is surgical.

In the author's material adnexectomy was done on the right side in 32 per cent of the cases, on the left side in 29.6 per cent, and bilaterally in 14.80 per cent; subtotal hysterectomy was added in 12.5 per cent of the cases. Any attempt to save the adnexa on the opposite side depended on their condition and to a lesser extent on the patient's condition and needs with regard to parity. Recurrence in the opposite tube was encountered in 3.9 per cent of the cases. The operative mortality was 1.56 per cent.

The author believes that intrauterine pregnancy compromises the chances of the patient acquiring a later pregnancy. He cites the fact that in 11 of the women in his material a later salpingographic examination showed that the remaining tube was occluded; however, he believes that this may in many instances have been the result of conditions preceding the surgical intervention.

JOHN W. BRENNAN, M.D.

Redell, G.: Parathyroprival Tetany and Pregnancy. *Acta obst. gyn. scand.*, 1946, 26:11.

On the basis of the literature and the study of 4 cases the author believes that in case of postoperative tetany the patient should be informed that if she becomes pregnant it is imperative that a series of serum calcium determinations be made frequently.

It is known that the serum calcium level often drops in pregnancy, and the calcium has been known to decrease as early as the third month. It is also known that the follicular hormone decreases the calcium content of the blood. Therefore it should be borne in mind that during pregnancy one must be on the watch for an exacerbation of tetany.

In 2 cases described the patients became pregnant during periods when they showed signs of tetany. In both of them the pregnancy, delivery, and puerperium were uneventful. In the other 2 cases the condition was less severe and here again there were no complications. There was no mention of the fact that calcium therapy was or was not used during the prenatal course.

CATHERINE B. HESS, M.D.

Wolff, J. R., and Limarzi, L. R.: Blood Disorders Associated with Pregnancy. *Am. J. Obst. Gyn.*, 1946, 51: 447.

In the past the obstetrician's main interest in the blood findings associated with pregnancy has been in the clinical interpretation of the commonly noted lowered hemoglobin level and erythrocyte count seen in healthy individuals during pregnancy. In more recent years, the association of pregnancy and the various blood disorders has gained attention, but unfortunately no use has been made of the sternal marrow findings. The hematologist, likewise, has not yet considered the problems of pregnancy in the light of the information obtained from bone marrow studies. It is only through co-operation of the hematologist and the obstetrician that such a relatively new idea can reach its proper place in clinical investigation.

Bone marrow biopsy is not the sole method of answer to hematological diagnosis. It is merely a part of the diagnostic "blood work-up," but it is an important one. The standard peripheral blood studies are still of major importance, and in many cases the sternal marrow findings may be only confirmatory. Yet peripheral blood studies, especially in pregnancy, often do not give sufficient information be-

GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Sandrin, G.: A Case of Supernumerary Megaureter (Un caso di megauretere soprannumerario). *Riforma med.*, 1946, 60: 7.

The author reports the case of a 4 year old female child who was admitted to the hospital with pain and tenderness in the right lower quadrant, obstipation, rapid pulse, and elevation of the temperature. Laparotomy revealed an anomalous second ureter on the right side which grossly resembled a loop of small intestine, but was connected with the pelvis of the kidney and showed a sphincterlike ureterovesical orifice. The structure was found to be distended with purulent urine.

Microscopic examination showed three muscle layers lined with mucosa similar to that of the bladder and covered with a serosal layer. Since the kidney was otherwise normal, surgery was confined to the removal of the anomalous ureter, and the patient left the hospital after an uneventful recovery.

The gross and microscopic morphology of the lesion are carefully described and the derivation is discussed

EDITH FARNSWORTH, M.D.

Hellström, J., and Romanus, R.: Ureterointestinal Implantation According to Coffey. *Acta chir. scand.*, 1946, 93: 439.

While interest in ureteral implantation in the intestine has been great, especially in America, and has given rise to a copious literature, this operation seems to have been relatively little resorted to in the Nordic countries and has been the subject of only brief reports.

The material derives from the Surgical Clinic of Karolinska Sjukhuset during the period from February 1, 1940 to November 15, 1945, and comprises 45 patients, 23 male and 22 female, ranging from 4 to 78 years of age. Altogether 89 ureters have been implanted according to Coffey's method I. Of these, 4 have been reimplanted; on 2 occasions double ureters have been implanted simultaneously; in 4 cases it was a matter of single kidney, and in 3 cases only unilateral implantation has been carried out; the operation was not completed because of the progress of the malignant process. (Since the material has been collected a further 3 patients with cancer vesicae have been operated upon for ureteral implantation, in 2 cases after cystectomy, and in 1 case in which the bladder was not removable.)

On the whole the cases may be classified in two groups; namely, (1) congenital or acquired states of the bladder, with complete incontinence or very frequent and painful urination, and (2) primary or secondary tumors of the bladder that can only be treated radically by cystectomy, or tumors for which ureteral implantation is indicated as a palliative measure.

Ureteral implantation according to Coffey's first method is an operation which, when performed with the right technique, is combined with a very low primary operative mortality.

In all of the cases except 2 the implantations have been performed in 2 stages, as a rule with the procedure commencing on the right side. Ureteral dilatation, even when very pronounced, has not been regarded as a contraindication, but rather as the opposite.

In no case has peritonitis or serious wound infection arisen. Four patients—all suffering from cancer vesicae—have died in the hospital, 2 of the original disease, and 1 patient each of rectal injury in connection with the cystectomy and of pyelonephritis. Thirteen patients have died after discharge, 8 of the original disease (cancer) and the others more or less because of the ureteral implantation which led to infection and dilatation of the ureters and pelvis. Infection and dilatation with impaired renal function had often existed, however, before the implantation. By means of repeated excretory urographies it was found that the dilatation of the ureters and pelvis which, as a rule, appears after the implantation generally recedes more or less completely later on. The condition of the survivors was good in 17, satisfactory in 9, and poor in 2 cases.

In certain cases, however, because of dilatation and infection, renal insufficiency which may have a fatal issue arises. On account of this and the discomfort of more or less frequent evacuations of the bowel which occur in a number of patients, ureteral implantation must be regarded as a serious operation that should be resorted to only when it is definitely indicated.

According to the author's own experience and to the data given in the literature, the ureteral implantation according to Coffey method I does not give worse, but rather better immediate and final results than other methods for ureteral implantation in the intestine, which as a rule are more complicated.

JOHN E. KIRKPATRICK, M.D.

Young, W. W.: Sclerosing Injection of Polycystic Kidney following Surgical Exposure. *J. Urol.*, Balt., 1946, 55: 323.

It is generally admitted that radical surgery, such as nephrectomy, is to be condemned except in rare instances. The pathological change in polycystic kidney warrants only a minimum of surgical trauma. The object of specific surgical treatment is to make room for renal parenchymal tissue with its vascular supply, which is being compressed and atrophied by multiple cystic intrusion.

When the patient, whose case history is presented below, required surgical intervention because of pain from unilateral cystic distention, it occurred to the author, although puncture and evacuation might

prove adequate for a brief period, an effort should be made to prevent the reformation of cysts, if possible. It seemed logical to instill a mild sclerosing agent into the emptied cystic cavities. Five per cent sodium morrhuate solution was selected.

Fish has reported 2 cases of solitary cyst of the kidney cured by aspiration and the instillation of 50 per cent dextrose solution; but as far as a careful search of the literature reveals, this type of procedure has not been proposed for polycystic kidneys.

A girl, aged 15, was first admitted to the hospital for urinary investigation following the discovery of palpable masses in both renal regions by her family physician. Intravenous pyelography a few days prior to admission revealed: "both kidneys equally enlarged with large pelvis of a similar shape, that is, the lower calyces have a normal contour but are slightly enlarged. The upper calyces are larger and show a tendency to concave pressure deformity. The appearance, however, is not entirely characteristic of cystic kidney (the kidneys have a smooth contour). The ureters are quite small and both make a right angle curve as they enter the pelvis. Excretion of dye was apparently normal. Conclusion: Probable congenital polycystic kidneys."

In the upper left quadrant a large mass could be palpated which extended down to the level of the iliac crest. This had a smooth, firm, elastic surface and the contour of a large kidney. In the right upper quadrant a similar mass, not quite as large, extended to a level just above the crest of the ilium. Both masses were fairly mobile. The nonprotein nitrogen was 38 mgm. per 100 c.c. of blood. The 2 hour phthalein output was 43, 27, 5, and 3 per cent or a total of 68 per cent.

Bilateral retrograde pyelograms, including a lateral view, demonstrated definite distortion of the enlarged, elongated calyces due to concave or "crescentic" defects in both kidneys. The upper major calyces appeared markedly narrowed compared with the minor calyces beyond. The diagnosis of congenital polycystic kidneys was established.

The patient failed to return for observation until about 21 months later. When she entered the office, her general physical contour suggested a full term pregnancy. In order to obtain any relief at all she had to remain in a recumbent position.

Physical examination again revealed all clinical abnormalities confined to the abdomen except for the blood pressure which was now 170-90. The entire left side bulged prominently, especially in the left lower quadrant. The abdominal wall was soft except over the large, immobile mass which completely filled the left side, extending from above the rib margins to and below the pubic ramus and symphysis. The surface of this mass was generally smooth, firm, and elastic with minor lobulations. There was slight tenderness over the whole mass when moderate pressure was exerted but there were no localized areas of acute tenderness. On the right, the findings were essentially similar to those noted on the previous examination. The right kidney ex-

tended down to just about the iliac crest, and, apparently, had proportionately grown no larger.

Cystoscopy was repeated. Fifteen minute differential phthalein output from the left kidney was as follows: appearance time, 13 minutes; excretion, 2 per cent; right kidney, appearance time, 11 minutes; excretion, 6 per cent.

Under general anesthesia, the left kidney was exposed through an oblique lumbar incision extending to just above the anterior superior spine. Before leaving her bed and again after the anesthesia had been administered, the patient received 5 c.c. of 8 per cent indigo carmine intravenously. The perirenal fat was minimal. On the grayish red surface of the hugely enlarged kidney there were numerous large, well demarcated cysts under considerable tension and a variety of smaller cysts of all sizes. The kidney was mobilized as freely, gently, and as completely as necessary for ample surface exposure. The lower pole protruded for a short distance into the true bony pelvis. With a large supply of Luer syringes, ranging from 10 to 50 c.c. in size, and a variety of needles ranging from 22 to 17 gauge, with both sharp and blunt bevel, aspiration and instillation of the individual cysts were undertaken. The aspirated fluid was turbid and grayish brown in color. It approximated the consistency of milk and passed readily through a 20 gauge needle. The cysts were evacuated as completely as possible, this being facilitated by gentle manipulation or pressure in various directions on the surface of the kidney.

Superficial cysts were observed to collapse so that deep concavities formed on the renal surface. As much as 70 c.c. of the fluid contents were obtained from each of several of the larger cysts. After aspiration of each of the larger individual cysts, the needle was held in place, the syringe detached, and another containing 5 per cent sodium morrhuate solution for instillation was applied. Many of the deep seated cysts were located easily by palpation although they were not discernible on the surface. On two or three occasions, the needles were inserted into the renal pelvis and essentially clear, light bluish green urine was obtained, substantiating the value of the preliminary use of indigo carmine. A total of 35 c.c. of sodium morrhuate solution was used, the quantity for each cyst varying with its size and the amount of fluid aspirated. Approximately 1 c.c. of solution was instilled for every 10 c.c. removed. Many of the smaller surface cysts were aspirated without injection, or they were simply punctured.

The kidney changed noticeably in size and conformation, diminishing from two-thirds to one-half of its original mass. The surface became flabby and loose. After the insertion of two small cigarette drains, the incision was closed in the usual manner with chromic catgut and silk sutures.

The postoperative course was uneventful. The temperature rose as high as 102.2°F. rectally during the first 4 days and remained normal after the fifth day. The patient had no more pain or greater discomfort than usually is experienced after renal

surgery. The incision remained uninfected and healed essentially per primam.

During the next 9 months the patient was observed personally on infrequent occasions. She soon returned to school and to her normal activities, being completely asymptomatic. The large left kidney, now much smaller than in its preoperative state, assumed a roughly spherical shape, causing moderate protrusion of the upper left abdomen; the lower pole reached a level just below the iliac crest. On November 14, 1941, the nonprotein nitrogen was 33 mgm. per 100 c.c. of blood and the 2 hour phthalein output was 14, 20, 14, and 10 per cent, a total of 58 per cent. Urinalysis was essentially normal except for a trace of albumin. The blood pressure was 140-90.

JOHN A. LOER, M.D.

Nyström, T. G.: Rupture of Kidney Tumors and Hydronephroses. *Acta chir. scand.*, 1946, 93: 513.

The author reports 2 cases of rupture of the kidney, a rare complication, occurring in a case of (r) hypernephroma and (2) hydronephrosis.

In the former case, the patient was a woman aged 51, who had been treated for hypertension and "kidney trouble" for 2 years before hospitalization because of a fall in the street, at which time she knocked her left side against the pavement edge. The admission diagnosis was possible ruptured spleen. The physical findings were temperature 37.1°C. (pr) and pulse 72. She was quite pale and presented considerable tenderness in the left upper quadrant, where an indistinct mass was felt. The urine revealed both albumin and microscopic blood particles. Exploratory laparotomy revealed a normal spleen, slight hemoperitoneum, and a distended left renal sinus with an enlarged, nodular kidney. The nephrectomy findings were: a renal sinus filled with fluid blood, clots, and pieces of tumor tissue and a kidney the size of a child's head. There was no extension of the tumor into the renal vein. The pathological diagnosis was Grawitz's tumor. (The patient died 6 months after operation, from generalized metastases.) Study of the operative specimen showed that the tumor had grown outward, penetrating the capsule and then breaking into the renal sinus; penetration into the pelvis or calyces had not occurred, which explained the absence of macroscopic hematuria.

The second case was that of a soldier, aged 23, whose first hospital visit in September, 1942, because of hematuria, revealed hydronephrosis on the left side with a question of periureteritis. In July, 1943, while pole vaulting, he disregarded back pains in the region of the left kidney and continued vaulting until the sudden onset of an intense, tearing pain in the back. Field hospital examination revealed marked tenderness, with slight muscle spasm in the left costovertebral angle. The urine was grossly bloody. Because of a relapse the day after admission, with an increase in the intensity of the symptoms, nephrectomy of the left kidney was done. The operative findings were: a renal sinus filled with fluid

blood and clots; the renal parenchyma measured about 1 cm. in thickness, the remainder of the kidney being a flabby, thin walled sac, containing fluid blood and clots, with a tear about 6 cm. long in its posterior wall. An aberrant artery was found, passing anteriorly over the ureteropelvic junction from the anterior surface of the lower pole of the kidney. There was no evidence of a periureteritis. The patient recovered and was returned to duty.

In a discussion of the factors involved in the clinical picture of rupture of a hydronephrosis, the following are considered:

1. Incidence, age, sex. Up to 1934, only 70 cases were reported. Although hydronephrosis is more common on the right side, ruptures occur twice as often in cases of hydronephrosis on the left side, probably because of the more exposed location of the left kidney. In a review of 70 collected cases, it was found that 44 occurred in patients between the ages of 10 and 40, and the patients more frequently were males.

2. Type of rupture. The cases were divided into: (a) partial ruptures which may heal or may develop into secondary traumatic cysts, and (b) total ruptures which were classified as: (1) ruptures extending to the capsula fibrosa, with a resulting perirenal pseudohydronephrosis; (2) ruptures including the capsula adiposa, resulting possibly in a pararenal pseudohydronephrosis; and (3) ruptures in which there is a single layered sac wall and the rupture extends out into the renal sinus retroperitoneally. The last is the most common type. In a few cases, the hydronephrosis was closely adherent to the peritoneum. One case of hydronephrosis rupturing into the cecum is reported.

3. Mechanism by which rupture occurs. When a hydronephrosis ruptures, the provoking trauma is often slight (as in a case in which rupture occurred when the patient jumped in bed). The rules applying to ruptures of internal parenchymatous organs also apply to cases of hydronephrosis. Most ruptures result from either compression or angulation. In the case of the former, the line of rupture is similar in direction to that of the applied force; in the latter instance, it is at an angle to the line of force. Compression of the hydronephrotic cyst from above downward will produce ruptures either in the anterior or posterior wall; compression from side to side or from the front in a backward direction will produce a rupture in the superior or inferior portion of the cyst. A rupture due to compression is more common than one due to angulation. Most authors maintain that the rupture of hydronephrotic cysts usually occurs in the posterior wall of the cyst and often in the inferior pole of the renal pelvis, especially after falls from a height.

The mechanism of rupture in the second patient is described by the author as follows:

In a pole vaulter, intra-abdominal pressure is increased as the athlete runs forward, with coincident increases of pressure within the hydronephrosis. As the body is swung up to clear the rail, it rotates

on its long axis and the kidney falls forward; as the psoas muscle and the vertebral column prevent it from swinging backward, the organ also rotates in a forward direction. If the ureter is fixed in abnormal contact with the pelvis, as is said to occur in most cases of hydronephrosis, this fixation will result in torsion because of the rotation; the pelvis cannot empty and a state of acute retention arises. As the jumping continues, the renal pelvis becomes more dilated with resulting increase in cyst tension until eventually compression occurs as the patient falls to the ground, and rupture of the hydronephrosis occurs. This would explain the pain felt by the patient as he continued to jump.

4. Symptoms. These depend on the type of rupture which has occurred. Commonly, there is a history of trauma to the abdomen or back, followed by a rapidly developing tumor in the region of the kidney, or there may be a renal enlargement, already in existence as a result of previous trauma, which also enlarges quickly following a second insult. Signs of peritonitis often predominate in some patients, in whom there is neither tumor nor hematuria because the hydronephrotic cyst which adheres to the peritoneum has ruptured directly into the peritoneal cavity. In some patients the acute symptoms subside, to be followed by pain after a somewhat asymptomatic period, which is indicative of a slowly developing tumor. Hematuria is not commonly found in cases of ruptured hydronephrosis; this is a result either of a tear through a nonparenchymatous area, or of retroperitoneal extravasation with associated ureteral compression. The statement that ruptured hydronephrosis has resulted in fatal reflex anuria is countered with the suggestion that the outcome was due rather to the fact that hydronephrosis, so often bilateral, had left an amount of kidney tissue incapable of secreting sufficient urine to maintain life.

The differential diagnosis includes consideration of ruptured spleen, renal calculus, ruptured ectopic pregnancy, and torsion of an ovarian cyst, and when there is a generalized peritonitis, only the history, if it is fairly typical, can suggest the etiological agent.

EUGENE J. AUDI, M.D.

BLADDER, URETHRA, AND PENIS

Pickerilli, H. P., and Pickerilli, C. M.: Ectopia Vesicae. *Austral. N. Zealand J. Surg.*, 1945, 15: 91.

Ectopia vesicae or exstrophy of the bladder is probably the worst and most distressing congenital malformation which afflicts human beings. Its frequency has been placed at about 1 in 50,000 births.

The most important defect is undoubtedly the osseous one. The pubic bones fail to unite, and each rectus muscle, being attached to the end of a pubic bone, is widely separated from its fellow below, which leaves a large triangular defect in the abdominal wall. The anterior wall of the bladder fails to join in the midline and the skin also fails to unite; the margins of the bladder unite instead with the external skin at each side. If the subject is a male,

there is always an accompanying complete epispadias.

To those having to deal with this surgical condition, it has seemed obvious that the first step must be to get the pubic bones to approximate one another in order to bring the recti together, and many attempts have been made toward this end, but without a single success by any surgeon, so far as can be ascertained.

In recent years implantation of the ureters into the bowel has been practiced so widely for other conditions that genitourinary surgeons have claimed that almost all patients with ectopia vesicae should be treated similarly. With the increasing development of the transplanting operation an easy way out of the difficulty is offered; but the authors want to make sure that this is the best for the patient in the long run. At least since Young's epoch-making operation, this method warrants serious consideration in every case. If this operation can be perfected so that urinary control can be relied upon definitely, then there will be no question as to the right method of treatment. However, if the operation fails to give control, is it still worth while? The authors think the answer is definitely "yes." In the male it is a difficult and prolonged procedure, but it gives results in that it can restore a patient to social circulation with surprisingly little disability.

If transplantation of the ureters is done, it still leaves the bladder and, in the male, the epispadias to be dealt with. If the bladder is left it is exposed to much superficial irritation, which eventually in a considerable number of cases (30%) causes malignant changes. The bladder must either be removed or closed by plastic operations. If it is excised as some surgeons recommend, what is to be done about the epispadias, remedy of which would then be practically impossible? Amputation of the penis has been suggested. The authors regard this as an unjustifiable mutilation. In addition, the possibility that the transplantation on one or both sides may not be successful must be taken into consideration. The results depend apparently upon the type of operation chosen and the skill and experience of the surgeon. There is, too, always the continuing risk of an ascending pyelitis, although it is claimed that this is a diminishing one.

There is the further consideration, of great importance in the authors' opinion, of the psychological effect on the patient of the persistence of an ugly irritable disfigurement or other obvious defect of the genital region, which has at all costs to be kept secret.

The authors discuss 2 cases treated satisfactorily by the Young operation.

JOHN A. LOER, M.D.

Mullenix, R. B.: Cystometry in the Study of Traumatic Neurogenic Bladder. *J. Urol.*, Balt., 1945, 55: 479.

A factual report of experience in the management of neurogenic bladder secondary to war wounds may be of value in the further study and solution of this vexing problem in civil life.

For a period of several months the author worked in association with the staff of an active neurosurgical center. During this period a large number of injuries of the spinal cord and cauda equina were cared for, under a stringent short term evacuation policy. In most instances tidal irrigation was not employed in this installation, suprapubic cystostomy having been performed when the intractability of the bladder dysfunction had been positively demonstrated. The final positive proof of intractability is, of course, the continued inability to void satisfactorily following the removal of the urethral catheter. Simple and positive though it may be, this method of trial has not infrequently been followed by ascending urinary infection with severe febrile reactions.

A preliminary appraisal of bladder function has been of value in preventing the subsequent occurrence of this complication. In an attempt to predict the ability or inability of the individual patient to void, cystometric studies were made in a large number of patients, an estimate of bladder function was arrived at, and the prediction was then proved to be correct or incorrect by actual trial without catheter. It has been possible to predict accurately the outcome in a high percentage of these patients, insofar as the time allowed for observation in this hospital would permit, and to plan treatment on this basis.

The value of cystometry in the civil practice of urology has been controversial. Although the author has no desire to enter this controversy, cystometry in his hands has been of great value in outlining the management of a large number of cases of neurogenic bladder due to wounds of the spinal cord and cauda equina. The usual technique of performance of cystometry has been expanded to yield more information regarding bladder dynamics and to visualize these findings graphically.

At the present time, repeated cystometric study is the most important diagnostic aid in the urologic study of the neurogenic bladder, and provides a permanent graphic record of progress over a long period of time. It may be helpful in the differentiation of bladder dysfunction based on neurogenic and obstructive changes. This may be particularly true in the appraisal of operative results in patients in whom both neurological and obstructive pathological changes may be coexistent or suspected. The many limitations of the procedure are also recognized.

This discussion and accompanying statistical data are presented with the full realization that they represent a small part of the problem of the neurogenic bladder. Periods of observation have been short, although the complete cycle of neurophysiological adjustment is very long.

The treatment of cord bladder, as such, is not strictly within the intended scope of this paper and has been referred to only briefly. The régime employed in this theater has been evolved on a basis of the requirements and limitations of the military service and has made possible the transportation and final definitive care of the largest possible number of patients.

JOHN E. KIRKPATRICK, M.D.

Williams, S.: Nongonococcal Urethritis in Australian Troops Stationed in Borneo. *Med. J. Australia*, 1946, 1: 693.

From 45 to 60 per cent of the cases of urethral discharge among Australian soldiers, in 1942, were of nongonococcal urethritis. Cases of nonspecific urethritis were then found wherein intracellular inclusion bodies were demonstrated in the urethral smears. Some workers were also able to culture pleuropneumonia-like organisms from the normal male urethra, from cervix uteri, and in 20 per cent of a series of nonspecific cases of urethritis in men. In view of these reports, a routine examination for inclusion bodies was made in all cases of nongonococcal urethritis at a military hospital in North Queensland, which revealed 8 instances of such bodies among the first 34 cases examined. When it was found later that nonspecific urethritis was occurring among troops stationed in the Netherlands East Indies, whose only contact was with the local Indonesians and Chinese population, it became of interest to see whether inclusion bodies could be demonstrated here also. The subjects investigated were Australian soldiers who had contracted their infection in widely separated areas in Borneo and had been evacuated to Morotai for nonmedical reasons.

Clinical features of these cases were: an incubation period of from 1 to 4 weeks; a thin purulent discharge, often present only in the mornings and persisting for from 7 to 20 days; an absence of dysuria or other symptoms; and lack of response to either sulfonamide or penicillin therapy. Altogether, 19 patients were examined, and in 10, typical inclusion bodies were found in the smears.

Laboratory findings, with Leishman's stain, revealed inclusion bodies in varying numbers. The bodies stained a bluish-purple, showing up clearly in the pale blue cytoplasm of the cells. They appeared as tiny, discrete, ovoid or rod-shaped particles arranged in small masses or clusters in the cytoplasm of large epithelial cells. They were never found in the leucocytes or in smaller epithelial cells; intranuclear forms were not observed. (Smears were obtained by introducing a platinum loop into the urethra and gently scraping cells and exudate from the mucous membrane).

On close inspection, inclusion bodies were found to have a characteristic morphology which differentiated them from the rickettsiae seen in murine and scrub typhus and from the elementary bodies of the psittacosis and lymphogranuloma inguinale group of viruses. The bodies are from 0.3 to 0.5 micra in size, and vary in shape, the most striking form being a minute ring with a delicate sharp outline and one or more thickenings at the poles. Vibrios, rods, and coccal forms were seen, these forms predominating in some smears. In every case, search revealed some cells with the ring forms. Extracellular forms, identical with the intracellular bodies were noticed, being very numerous in 1 case. Smears were taken on admission, then every 2 or 3 days until the patient was discharged. Inclusion bodies were

present in decreasing numbers during the first week and were usually absent in the second week.

This disease is prevalent throughout Australia, according to the author, who concludes from the random selection of this small group of cases that it also has a wide distribution in Borneo and possibly through the Netherlands East Indies. Information about the transmission of infection is incomplete as no adequate survey of female contacts has yet been published. On the basis of the morphological features seen in these cases, it is tentatively suggested that the inclusion bodies represent an intracellular phase of the pleuropneumonia-like organism which has been shown to be present in a proportion of cases of nongonococcal urethritis.

EUGENE J. AUDI, M.D.

Metcalf, M. M., and Ganem, E. J.: Cancerous and Preamerous Lesions of the Penis. *J. Urol.*, Balt., 1946, 55: 486.

The authors make the following observations on penile neoplasms, as dictated by their clinical and pathological characteristics:

1. Though the penis is one of the most often handled parts of the body, neoplastic disease is often well advanced when it is brought to the attention of the physician.

2. Penile cancer is virtually limited to the uncircumcised.

3. The same radical measures which are used elsewhere in the body must be used in the treatment of new growths of the penis and the inguinal lymph nodes must be studied microscopically to rule out the absence of malignancy.

The incidence of penile malignancy is low. At the Squier Urological Clinic, in New York, the incidence is 1 case in every 1,000 admissions; at the Mayo Clinic, Rochester, Minnesota, 0.3 per cent of all cancers in the male are of this type; and at Johns Hopkins Hospital, in Baltimore, 3.5 per cent of all malignancies were penile cancer. The disease is most common in the Far East and in the Orient, and it is seen more frequently in the Hindu than in the Mohammedan. The latter practices circumcision, although not in infancy as in the Jewish ritual, but between the third and tenth year. The only instance of penile cancer in a circumcised Jew is that reported by Dean, and this occurred on the glans which was treated for a sore by an actual cautery.

With these facts in mind, and the apparent role of inspissated smegma as an etiological agent in penile cancer, the authors insist on infant circumcision except in instances of hypospadias, in which the preputial fold is of importance in surgical plastic procedures.

Penile cancer occurs most commonly between the ages of 40 and 70 years; the youngest patient in the series reported was 30 and the oldest 82 years of age. It is emphasized that penile lesions with a positive serology must be studied microscopically to prevent the inoperable extension of a nondiagnosed neoplasm during antitubercular therapy and, too, that ill

healing adult circumcision wounds must be regarded with suspicion.

The duration of symptoms prior to operation varied from 2 months to 5 years.

The usual site of origin is on the glans at the corona or sulcus, and the lesion is most often a squamous cell epithelioma.

The lesions are described in detail, both as to appearance and location, and a sketch is included which clarifies the subject. The lesions most commonly encountered are:

1. *Leukoplakia*. A patch of keratinization on the glans, and there is characteristically no induration or ulceration.

2. *Erythroplasia of Queyrat*. A red, velvety, and slightly thickened patch on the glans with or without a central ulcer.

3. *Paget's disease of the penis*. A small erythematous patch of long duration with final ulceration. This lesion may appear on the shaft of the penis since it originates only in the apocrine glands which are not present on the glans.

4. *Bowen's disease*. A lesion of the glans characterized by single or multiple conglomerate, dull, red, scaly papules or nodules with rolled borders. The lesion can resemble clinically that of Queyrat or Paget.

Epithelioma of the penis usually develops either on the glans, or at the coronal sulcus, and may have been preceded by an area of leukoplakia, erythroplasia, or Bowen's disease, which may have been hidden by a phimosis. The majority appear either as papillary or indurated ulcerative areas. The symptoms are those of a painless papillary or indurated area on the glans, prepuce, or at the corona. This lesion is refractory to local treatment and a secondary infection, accompanied by a foul smelling discharge, soon develops. Inguinal adenopathy is due either to inflammatory or neoplastic change secondary to the primary focus.

In the authors' series, 42 per cent of the 19 cases reported revealed neoplastic extension to the inguinal nodes, and it is emphasized that absence of palpable nodes does not rule out cancerous involvement. Too, extension may follow the route of the "vertebral vein system" into which the malignant cells gain access by infiltration of the dorsal vein of the penis. This route explains the occasional cranial, thoracic, or femoral metastasis with no local recurrence following surgery.

It is advised that the diagnosis be made by biopsy of all papillary or ulcerative lesions, and followed immediately by surgery.

The treatment is dependent upon several factors and, in the series reported, the following treatment and disposition were observed.

1. Six patients had a one-stage penile amputation with groin dissection, and varying combinations of with groin dissection, and varying combinations of with x-ray, or radium. Of this group, 5 are well, and are without evident recurrence 6 months to 9 years postoperatively; 1 patient died within 3 months.

2. Partial amputation without groin dissection but with postoperative irradiation was performed in 8 cases. In this group, 3 patients died of unrelated causes and presented no evidence of recurrence. Of the 5 remaining, 1 patient developed a recurrence 2 years later, 1 has not been followed, and 3 patients are well 10 months to 11 years later.

3. Two patients were treated by circumcision, but these could not be followed.

4. Three patients were definitely inoperable and all 3 died within a year.

5. One patient was treated by means of the high frequency current, but could not be followed.

Taking the series as a whole, 3 individuals were lost in the follow-up and another 3 died of other causes, so that these authors report 13 carefully followed and evaluated cases. Of these, 3 were inoperable and died, recurrence was seen in 2 instances, and 8 patients are well 6 months to 11 years post-operatively. The number of 5-year cures in this group was 4.

The authors report, in addition, 4 instances of secondary penile cancer. One patient, 71 years of age, had a papillary adenocarcinoma of the kidney with metastasis to the penis, involving the corpora cavernosa; 2 patients had primary lesions in the bladder, and the fourth patient had a penile lesion secondary to an adenocarcinoma of the rectum.

In a review of the literature, the authors found a total of 22 cases of secondary neoplasm of the penis.

The present paper is an excellent review of the subject of penile malignancy; it gives a concise picture of the disease and its treatment, and is profusely illustrated. ROBERT LICH, JR., M.D.

GENITAL ORGANS

Mathé, C. P.: Lymphosarcoma of the Testicle. *J. Urol.*, Balt., 1946, 55: 530.

Lymphosarcoma of the testicle is a rare tumor. It occurred 4 times in 400 testicular malignancies at the Mayo Clinic, Rochester, Minnesota, and once in 34 cases of testicular tumor at the Southern Pacific General Hospital in San Francisco. This is a highly malignant and rapidly fatal tumor of youth, although the aged are not immune, and it may occur primarily or secondarily, unilaterally or bilaterally.

The case reported is that of a 63-year-old individual who did not present a particularly significant past history and whose immediate findings were limited to an enlarged indurated left testicle. The removed testicle weighed 186 gm., and on section the greater portion of the testicle was replaced by tumor, though still limited by the tunica propria. The tumor was of uniform lymphoid consistency, grayish in color, with hemorrhagic areas. Histologic sections showed infiltrating tumor cells of lymphocytic type extending between and into the seminiferous tubules. There were no teratomatous elements found.

The operative wound healed satisfactorily, and 3 months later the patient returned with a recurrence

of the tumor at the site of the severed cord and multiple subcutaneous nodules over the entire body. A biopsy of the subcutaneous nodules showed tumor cells similar to those found in the excised testicle, though of greater activity.

The author discusses the possible etiology of this testicular tumor and its mode of dissemination, which is lymphogenous in a caudocranial direction by way of the lymph glands of the spermatic cord and those of the retroperitoneal, mediastinal, and left supraclavicular regions, respectively. However, that the tumor is not necessarily confined to the lymphatic system is mentioned, and blood stream metastasis is discussed.

The symptoms and diagnosis are reviewed, and the possibility of retroperitoneal lymphatic involvement with ureteral pressure in this type of tumor, is emphasized. The diagnosis is made by the presence of a testicular mass.

Though the literature reveals that only 5.5 per cent of individuals with a testicular tumor live for more than 4 years, in patients with lymphosarcoma there is even a less favorable prognosis.

The present accepted methods of treatment are (1) orchectomy with surgical excision or irradiation of the regional lymph areas, and (2) irradiation alone. The early surgical excision of the involved organ is considered imperative. It is noted that in less than 15 per cent of the recorded cases did orchectomy precede extension. It is further noted that orchectomy in the presence of established metastasis is equivocal as it may merely hasten the process. In addition, the magnitude of the surgical procedure necessary to remove the lymph areas contraindicates its use; however, it is advisable to clamp and ligate the vascular pedicle first at the external ring to prevent dissemination of malignant cells. The wound is bathed with alcohol to destroy any escaped tumor cells.

Frequent postoperative examinations for metastasis are important, and recurrences should be treated with irradiation, as was done in the case reported by the author. In this instance there was an immediate regression of the secondary tumor, although an increase of the secondary nodules followed, in spite of continued irradiation, and at the time of the author's writing the outlook for his patient was grave. ROBERT LICH, JR., M.D.

Pendergrass, E. P., Chamberlin, G. W., Selman, J., and Horn, R. C., Jr.: The Management of Malignant Tumors of the Testis. *Am. J. Roentg.*, 1946, 55: 555.

The authors studied 43 patients, all of whom were definitely known to have had malignant tumor of the testis. They classify the tumors as either homologous, composed of uniform cells without organoid arrangement, and heterologous, made up of a mixture of tissues showing various types and degrees of differentiation. Among the 20 homologous tumors in the series were 13 characteristic seminomas. The big incidence of these occurred in the fourth decade,

while the corresponding incidence of the heterologous tumors was spread between the third and fourth decades.

The tumors occurred approximately twice as often on the right side as on the left. The most frequent complaint on admission was a painless scrotal mass, and one-third of the patients had testicular pain. Thirty-eight per cent of 37 patients upon whom data are available had objective clinical evidence of metastases. In all, 58 per cent of the patients showed evidence of metastases at some time. Lumbar pain was an ominous symptom. The tumor spread first to the lymph nodes about the celiac axis by way of the lymphatics accompanying the spermatic vessels; these retroperitoneal metastases frequently gave rise to abdominal cramps and gastrointestinal disturbances.

Only one of the tumors developed in an undescended testis. Breast changes were observed in 9 patients. Hormone assays were done in 6 patients with breast symptoms, and 5 showed positive Freedman tests. Chest roentgenograms demonstrated pulmonary or mediastinal metastases in 13 patients. Excretory urograms revealed retroperitoneal metastases in 60 per cent, chiefly by obliteration of the psoas shadow by a soft tissue mass and displacement of the renal shadow on that side. The return of renal function, apparently due to reduction in size of the metastatic masses around the renal pelvis, was observed in post-irradiation roentgen studies. In several patients there was displacement of the stomach, duodenum, or colon. Urinary gonadotropic hormone bioassay should be carried out before therapy is begun. A positive test appearing after treatment is significant if done within 8 months of orchiectomy. Beyond that time follicle-stimulating hormones may be indicative either of castration effect or of recurrence. A negative test has no significance, except insofar as the absence of follicle-maturing hormone improves the prognosis. In this series no correlation could be established between the results of bioassay and the patient's clinical course. All patients with malignant testicular tumor should have the benefit of irradiation and orchiectomy. The radical regional lymphatic dissection operation of Hinman was not done in this series. During irradiation, weekly leucocyte counts and hemoglobin determinations should be done, and the former should be kept above 1,000. Progressive loss of weight is often associated with a poor prognosis. All patients known to have died of the disease succumbed within 3 years, and more than 50 per cent died within 1 year. The authors believe, therefore, that a "five year survival" is a good indication of prognosis.

In patients free from demonstrable metastases on admission, and receiving conventional therapy (at least 1,000 roentgens delivered to the testis preoperatively), no statistically significant difference can be demonstrated in the five year survival with homologous and heterologous tumors. There is no significant difference in the five year end-result in the groups receiving preoperative or postoperative irradiation. One of the authors believes that pre-

operative irradiation should be seriously considered. It is advisable to continue administering preoperative irradiation on the basis of clinical diagnosis alone until sufficient experience is obtained to evaluate the efficacy of this procedure. However, irradiation of the primary tumor does alter its cellular structure and thereby renders microscopic diagnosis more difficult. In the absence of clinical metastases, the authors suggest the following plan of preoperative treatment.

The factors are 200 kilovolts, 15 milliamperes, 0.5 mm. copper, plus 1 mm. aluminum, and 80 cm target-skin distance. The half value layer is 0.9 mm copper. The fields are planned so that the lymphatic drainage channels of the torso on either side of the midline of the body from the supraclavicular regions to the symphysis pubis, and the inguinal regions and pelvis are irradiated. The portals should extend at least 10 cm. to either side of the midline. The irradiation is started in the peripheral fields, and on successive days the treatment is directed over the adjacent fields. For instance, the first day, irradiation is given over field 1, the second day over field 2, and third day over field 3. When treatment of all of the fields has been completed, the fields are again treated in the same order. The daily increments and the number of fields treated in one day should depend on the ability of the patient to tolerate the radiation. Each field should receive a total dose of 1,600 roentgens in air.

If treatment is to be applied to the primary tumor, it should not be started until all of the other fields have received at least 1,000 roentgens. The involved testicle should be protected as much as possible from primary and secondary radiation by means of a lead cup. The amount of radiation applied to the involved testicle will depend on whether one wishes to destroy the tumor, which will require considerable irradiation, or merely modify its cellular appearance, which can be accomplished readily by 1,000 roentgens.

The operation can be carried out at any time following completion of the roentgen therapy, either immediately or after a delay of a few days to 3 weeks. The authors believe that a simple orchiectomy is to be preferred to a more radical procedure.

If the patient has clinical evidence of metastases, irradiation in that area should be carried to the limit of skin tolerance. Wherever 400 or 1,000 kilovolt therapy is available, it may be beneficial to use such therapy, if the metastatic lesions do not respond to 200 kilovolt therapy.

If postoperative therapy is the method of choice, the following program is presented as a satisfying procedure:

On the strength of clinical evidence of a malignant tumor, the testis should be removed with the least possible trauma, preferably by preliminary ligation and section of the spermatic cord. A roentgen examination of the chest, an intravenous urogram and bone survey, if indicated, should be made preoperatively. As soon as possible after surgery (2 or 3 days

afterwards if the patient can be brought to the department) a course of deep roentgen therapy should be started over the lymphatic drainage areas. The primary drainage areas, situated about the celiac axis, should be completely treated first, followed by successive fields upwards to include finally the left supraclavicular area, and downwards to include the inguinal regions and pelvis. The recommended treatment factors are: 200 kilovolts, 15 milliamperes, 0.5 mm. copper, 1 mm. aluminum, 80 cm. target-skin distance. The half-value layer with these factors is 0.9 mm. copper. The treatment fields should extend at least 10 centimeters to each side of the midline. Each field, anteriorly and posteriorly, should receive at least 1,600 roentgens, measured in air, in divided daily doses. The increase in dosage over the previous conventional treatment is based on the observed difference in radiosensitivity of the various pathologic types, especially the poor response of metastases from the heterologous tumors. In patients with known metastases, the total dosage should be carried to the limit of skin tolerance.

In summary, the overall five year survival rate in the series of 43 patients was 42 per cent, and in patients free from demonstrable metastases, 71 per cent. In patients with metastases the corresponding result is 30 per cent. Four patients (of a total of 24) who had clinically evident metastases at some time during their illness are alive and well 5 to 16 years after their last treatment; in one case there was a supraclavicular mass. There was no difference in end results between preoperative and postoperative irradiation. Preoperative or immediately postoperative irradiation is recommended in all patients with a malignant tumor of the testis regardless of the presence or absence of clinical evidence of metastases.

MISCELLANEOUS

Jacobi, H. G.: Streptomycin in the Treatment of a Case of Persistent Urinary Infection. *N. York State J. M.*, 1946, 46: 883.

The author reports a case of prolonged urinary infection extending over a period of almost 6 years following a transurethral prostatic resection. During this period 4 operations were performed for the removal of calculi from the kidney and ureter. The infecting organism was at first the bacillus proteus which was subsequently displaced by the bacillus pyocyaneus.

Sulfonamides and penicillin were ineffective in controlling the infection.

Twenty-four hours after the institution of streptomycin therapy the urine became clear and cultures were negative. Repeated cultures for 5 months thereafter still continued to show a sterile, clean urine.

The streptomycin was dissolved in pyrogen-free distilled water and given intramuscularly at 3 hour intervals during the first 3 days and at 4 hour intervals thereafter for a total period of 10 days. The first two doses contained 500,000 units each (in 3 c.c. of water) and the remaining doses 250,000 units each (in 2 c.c. of water).

Blood serum and urine levels of streptomycin were studied during the course of the therapy. It was found that streptomycin is excreted more slowly by the kidneys than penicillin. The blood levels are, therefore, much more stable and can be maintained more readily at an effective level by injections at intervals of 4 hours or even longer. The effectiveness of streptomycin increases with an increase in the pH of the urine.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Ferrandu, S.: A Contribution to the Study of the Pathogenesis of Idiopathic Osteopsathyrosis (Contributo allo studio della patogenesi dell'osteopsatrosi idiopatica). *Chir. org. movim.*, 1943, 29: 271.

According to the time of origin of idiopathic osteopsathyrosis, various terms have been applied to the same pathological process; viz., osteogenesis imperfecta, congenital osteopsathyrosis, and essential fragility of the bones.

Osteopsathyrosis may be essential, also called idiopathic, or secondary to a number of other conditions, such as simple or inflammatory osteoporosis, rickets, osteomalacia, Paget's disease, fibrocystic osteitis, locomotor ataxia, syringomyelia, poliomyelitis, neoplastic disease of the bones, scurvy, syphilis, or tuberculosis of the bones.

Idiopathic osteopsathyrosis is also called Lobstein's disease.

Vrlick's disease, or osteogenesis imperfecta, has in common with the condition under discussion the extreme fragility of the bones, but it originates during fetal life and does not carry the characteristic hereditary features; furthermore it causes dwarfism with micromyelia and is responsible for a poor general condition.

Periosteal dysplasia or Porak-Durante's disease causes signs nearly identical with those of osteogenesis imperfecta.

The diagnosis of osteopsathyrosis is based on the presence of three signs: (1) blue sclerae, (2) extreme fragility of the bones, and (3) impaired.

Nontraumatic deformities of the skull are very frequent. Kyphoscoliosis is also encountered in numerous instances. While the cortex is abnormally thin, there are no changes in the normal architecture of the osseous trabeculae. Usually one finds an abnormal fragility of the nails and hair, lacunae in the dental cement, abnormally small and translucent teeth, and short bodies with relatively elongated hands and feet.

Of innumerable etiologic factors only thyroid dysfunction seems to constitute a positive finding, the basal metabolism rate usually being increased by 30 per cent. Cortical suprarenalism may also be considered, but the role of the spleen in the pathogenesis of osteopsathyrosis is rather dubious.

JOSEPH K. NARAT, M.D.

Cohn, I.: Dyschondroplasia. *Ann. Surg.*, 1946, 123: 673.

A brief review of the literature leads to the theory propounded in 1928 by Murk Jansen, which the author believes warrants general acceptance.

Six different processes, and probably more, have to co-operate harmoniously in order that the bones

shall attain their proper size, shape, structure, and composition, when completing their growth. These processes are resorption, tubulation, cancellatum, cell division, cell enlargement, as well as differentiation.

"Sometimes one or more of these processes will be delayed with regard to the other processes during a shorter or longer period, and the dissociation of each of these processes evokes its own characteristic symptom.

"The clinical picture is characterized by its extreme polymorphism. In some cases only a single bone is found to be affected, and in others the condition presents itself on both sides."

A retardation of tubulation results in a funnel shaped metaphysis, and exostoses are concluded to be the result of partial retardation of tubulation.

Personal observations of cases over a period of 15 years include 6 individuals in two generations of one family, whose photographs and roentgenograms are presented in the original article to bear out the conclusions. Dyschondroplasia is a hereditary retardation phenomenon transmitted without regard to sex. It affects shafts of long bones near the ends of the diaphysis, and changes in the epiphyses are entirely secondary. Involvement may be limited to a single bone or may be diffuse in all bones laid down in cartilage. Roentgenographic evidence of dyschondroplasia may be absent in early infancy and appear later, but progress occurs only until full bone growth is accomplished.

True cases of dyschondroplasia manifest evidence of dissociation phenomena which may be both partial and complete, as evidenced respectively by wide metaphyses and spurlike exostoses.

This condition is not a disease but attests to a lack of harmony among the various processes of normal bone growth, and surgical interference is warranted only when there is mechanical interference with joint function, and after epiphyseal growth has ceased.

FRANCES E. BRENNER, M.D.

Sellaroli, M.: Osteoarticular Tuberculosis and Trauma (Tuberculosis osteoarticolare e trauma). *Chir. org. movim.*, 1943, 29: 259.

Osteoarticular tuberculosis after trauma affects the knee, foot, elbow, and shoulder, in given order as to frequency.

Of 1,000 patients with tuberculous osteoarthritis treated by the author, 318 were men and 682 women. In 14.7 of the male patients trauma was responsible for the condition, while the corresponding percent for the female patients was 12.3. Among the entire 1,000 cases, trauma was suspected as the cause of the condition in 13.1, or 13.1 per cent. Apparently a traumatized region may be considered a site of minor resistance where tubercle bacilli find a favorable medium for growth. JOSEPH K. NARAT, M.D.

Corsi, G.: Evolution of Tuberculous Osteitis of the Femoral Neck (Evoluzione ed esiti dell'osteite tuberculare del collo del femore). *Chir. org. movim.*, 1943, 29: 153.

Tuberculosis of the neck of the femur is gradually becoming less frequent. The condition is caused by an infected embolus which becomes lodged in one of the terminal arteries. Therefore the condition is found most frequently in children because the collateral arteries develop during adolescence.

Two types of tuberculosis of the neck of the femur may be distinguished, caseous and fungous.

Topographically, 4 groups of the lesion may be differentiated: (1) lesions of the lower cervicodiphyseal arc, (2) lesions of the juxtaepiphyseal region, (3) lesions of the bulbometaphyseal region, and (4) lesions of the subtrochanteric metaphyseal region.

The technique of surgical procedure is difficult because the lesion is located deep within the articular capsule. Moreover, an operation carries with it the danger of spread of the infection with a resulting panarthrosis or general dissemination of the tuberculous process which may lead to miliary tuberculosis.

The evolution of the process depends on its invasive tendency and the resistance of the body.

Among 29 cases treated by the author, a cure with good mobility was obtained in 17, and an ankylosis was produced by tuberculous coxitis in 12.

The author advocates conservative treatment with traction and the application of a body cast.

JOSEPH K. NARAT, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Adson, A. W., Young, H. H., and Ghormley, R. K.: Spasmodic Torticollis. Severe Organic Type Treated by Combined Operation, Rhizotomy, and Fusion. *J. Bone Surg.*, 1946, 28: 299.

The term "spasmodic torticollis" is applied to a group of manifestations consisting of muscular spasms of one or more muscles of the neck. These manifestations may result from emotional instability; from an organic lesion affecting the basal nuclei, peripheral nerves, or muscles; or from a combination of these factors. Not infrequently the discomfort and disability become so severe that surgical intervention is required.

Spasmodic torticollis may involve one or more muscles of the neck and the spasms may be tonic or clonic, or a combination of both. At the onset, the muscles on one side may be affected but the condition may progress to involve the muscles on both sides. The muscles usually affected are those supplied by the spinal accessory nerves and the motor branches of the upper three cervical nerves. The sternocleidomastoid, the trapezius, and splenius muscles are the ones which usually produce the deformities of which patients complain.

The most difficult problem is to determine whether or not the manifestations are of psychogenic or or-

Fig. 1. a, The anatomic relationship of the upper three cervical nerves to the vertebral artery and spinal accessory nerve. b and c, The bilateral rhizotomy of the first and second cervical nerves and the motor root of the third cervical nerve.

ganic origin. It is extremely important to make this distinction because surgical procedures are not justified in the psychogenic type of case. It is necessary to determine the presence of any previous cerebral or meningeal diseases or injuries to the brain, nerves, or muscles. If any such diseases have occurred, they would point toward an organic basis for the development of the patient's symptoms. Since types of spasmodic torticollis may overlap, a conservative course of treatment should be employed first in all cases. By conservative treatment the authors mean the use of a medical regimen before any surgical procedure is advocated or performed. Their experience with conservative treatment of spasmodic torticollis has not been encouraging particularly in cases of the organic type.

When conservative measures fail and the symptoms are severe enough to produce pain and interfere with normal activity, operation must be considered, especially if an organic basis for the symptoms has been found. The authors devised an operative procedure which included bilateral intracranial section of the spinal accessory nerves and bilateral rhizotomy of the upper three cervical nerves with the introduction of a bone graft which had been taken from the ilium and placed in the occipitocervical space. The graft is shaped so that it can be transfixed to the posterior inferior surface of the occipital bone and placed laterally over the ends of the first and second cervical laminae and lateral to the spines of the cervical vertebrae over the third, fourth, and fifth cervical laminae.

The authors have found that bone from the iliac crest is most suitable for the bone graft. They prefer bone from the anterior portion of the iliac crest as a

longer piece of bone can be obtained therefrom than from the posterior portion. The graft is then split longitudinally. Before placement of the graft, holes are drilled in both upper ends in order to pass the wire through the graft as well as through the holes previously made in the skull lateral to the midline. Half of the graft is placed on each side of the vertebra to act as a roof over the spinal canal. The wires are passed through the two pieces of the graft and the holes in the occiput, and are twisted until they hold the graft snugly against the occiput and atlas. The grafts may be trimmed along their borders to ensure accurate fitting against the other cervical vertebrae.

Where a sufficient amount of lamina is left, the edge of the graft can be placed firmly against it, and when the upper end of the graft is fixed, the danger of slipping is minimized. The lower end of the graft is held in place by suture of the muscles firmly over it.

After closure of the wound a plaster cast is applied. This must cover the head, neck, shoulders, and most of the thorax. It should be applied carefully and padded well, but not too heavily.

Two weeks after operation a window is cut in the cast and the sutures are removed. Care must be taken to see that the cast is not weakened at this stage. If it is weakened, it should be reinforced. The cast should be worn from 10 to 12 weeks. After its removal a metal and leather collar is made, and worn an additional 3 months. If at the end of 3 months roentgenograms show solid union of the grafts in the occipito-cervical region, the support may be discontinued. If sufficient union has not taken place, the support should be continued until union is complete.

In view of the late results in 2 of the cases the authors believe that the combined operation, bilateral intracranial section of the spinal accessory nerves and bilateral rhizotomy of the upper three cervical nerves, particularly of the anterior roots, with the introduction of a bone graft at the same operation, is indicated for patients who have marked muscular spasm on both sides, for those who are compelled to do manual labor, and for those who have large heads. The major operation on the nerves can be employed without a bone graft for patients whose occupations do not require manual labor. If difficulty in the forward tilting of the head with impairment in breathing, swallowing, or speaking should occur, a subsequent fusion operation may be performed. This combined operation of section of the nerves and fusion of the bone is a major procedure and should be employed only when the patient is incapacitated as the result of spasmodic torticollis.

Venable, C. S., and Stuck, W. G.: Muscle Flap Transplant for the Relief of Painful Monarticular Arthritis (Aseptic Necrosis) of the Hip. *Ann Surg.*, 1946, 123: 641.

Degenerative monarticular arthritis of the hip joint is caused in adults predominantly by injuries or pathological changes of the head of the femur. Contusions, fractures, traumatic dislocations in-

adequately treated Perthes' disease, and slipped femoral epiphyses are some of the causes of degenerative arthritis of the hip joint. The pathological changes are caused by interruption of the blood supply to the head of the femur, which results in ischemic necrosis of the bone and cartilage. Most cases of monarticular degenerative arthritis of the hip develop in the fourth and fifth decades of life. The symptoms are: increasing stiffness, early loss of rotation and abduction of the femur, a catching sensation, pain, and eventually flexion and adduction deformity.

The treatment of these conditions includes the following: conservative measures (physical therapy, traction, plaster cast, crutches) which only provide temporary relief; manipulation of the hip under anesthesia to correct the deformity; and surgery. Several operative procedures are recommended. Osteotomy of the femur changes the axis of weight bearing. Sir Robert Jones recommended trimming of the marginal osteophytes and called this procedure "cheilectomy." Magnusson calls the same operation "joint débridement." Whitman and Colonna excise the head and reconstruct the hip joint. A painless but unstable hip and considerable shortening of the leg is usually the result. L'Epicopo forms a bone block from the ilium to the neck of the femur. Arthroplasty, using viscoloid, steel cups, pyrex glass, bakelite, vitallium, or fascia, increases the motion in the hip joint, but does not relieve the pain sufficiently to satisfy the patient. Fusion of the hip by bone graft or by means of the Smith-Petersen nail results in a permanently stiff hip.

David Brainard, who drilled the head and neck of the femur 90 years ago, and thus facilitated the passage of the capillaries into the neck of the femur, reported the immediate relief of pain. Following this observation, the author transplanted a portion of the vastus lateralis muscle into a longitudinal slot cut into the anterior surface of the neck of the femur. After the operation, the patient had immediate and lasting relief of pain. Of the 27 patients operated upon, 26 allegedly have gained marked pain relief which lasted as long as 2 years. A number of x-rays are presented illustrating preoperative findings and cup operations. No detailed history, preoperative and postoperative findings, or follow-up observations are given. GEORGE I. REISS, M.D.

Ponseti, I.: Pathomechanics of the Hip after the Shelf Operation. *J. Bone Surg.*, 1946, 28: 229

The article presented is based upon 68 patients (31 males and 37 females) with dislocation of the hip joint. There were 61 congenital dislocations, 7 of which were of prenatal origin, and 54 of postnatal origin. Nine were congenital subluxations. The average follow-up period was 7 years, and the ages of the patients varied from 2 to 36 years. In 42 hips, the shelf was built at the primary acetabulum; in 23, it was constructed at the secondary acetabulum. In 12 hips, the femoral head was completely dislo-

cated and there was no secondary acetabulum. In 5 hips, in which a shelf operation was done, the greater trochanter was detached together with its muscle attachments and reattached from 1 to 3 cm. down over the lateral aspect of the femur.

The telescoping sign disappeared after the operation in 51 cases and persisted in 1 case of posterior dislocation. The Trendelenburg sign was observed in 73 hips prior to the operation. In 61 hips, the sign persisted after the operation. Fifty-one hips were free of pain before the shelf operation and remained free of pain after the operation. In 7 cases, there was pain in the hip on admission, but it disappeared after operation. Fourteen hips were pain-free before, and became painful after, operation.

In all of the patients, the distance between the center of the femoral head and the line drawn through the longitudinal axis of the sacrum was measured on the anteroposterior roentgenogram. On the average, this so-called Y-co-ordinate was found to measure 5.5 cm. It was found that if the Y-co-ordinate of the hip with a surgically created shelf measured less than 1.2 cm., as compared with a normal one, the functional result was satisfactory. The greater the difference between the Y-co-ordinates, the more pronounced was the limp. The best results were found in hips in which the femoral head was close to the line of gravity; they did not depend upon the length or thickness of the shelf. The ultimate results were the same regardless whether the greater trochanter was or was not surgically displaced downward over the lateral aspect of the shaft.

In conclusion, it is stated that in children under the age of 4, with congenital dislocation of the hip, the shelf operation is contraindicated. The development of the hip muscles and the prolonged position of the limb in abduction and inward rotation were sufficient to maintain the femoral head in the acetabular cavity. For children over 4 years in whom the closed reduction has failed, an open reduction with the construction of a shelf may be indicated. It is emphasized that the surgeon should not depend too much on the shelf, but rather concentrate on the proper position and maintenance of the femoral head within the acetabular cavity. In adults, the shelf operation contributes additional support to the femoral head and relieves the strain on the capsule and ligaments of the hip joint, thus relieving the patient's pain. The limp, however, may persist.

In cases in which the femoral head cannot be reduced into the primary acetabulum, a well performed Shanz osteotomy gives good functional results. If a Shanz osteotomy is performed on a child, the angle of the osteotomy will gradually disappear and the femur may become completely straight as the patient grows. Therefore, it is better to observe these patients until puberty and if pain occurs, to perform the Shanz osteotomy at that time. In young patients with irreducible posterior dislocations in whom the femoral head tends to become displaced upward and backward under the iliac wing, a Shanz osteotomy is indicated and may be

repeated at a later date. The anterior transposition of the femoral head, in cases of posterior dislocation of the hip joint, is considered very traumatic and should be abolished altogether. Reaming and deepening of the acetabular cavity usually results in stiffness of the hip joint. GEORGE I. REISS, M.D.

Aldredge, R. H.: Indications for the Syme Amputation. *Surg. Clin. N. America*, 1946, 26: 422.

The Syme operation was first described in 1843, and many conflicting reports on its merits have been presented at intervals ever since. To evaluate these opinions the author divides the cases into (1) war cases, or those which are or recently have been infected, and (2) civilian, or clean cases.

In World War I many of the unhappy results occurred in cases in which surgery was done in the presence of, or soon after, infection—therefore in poorly selected cases. Experience in the recent war has proved that this cause of failure can be eliminated, and then good results can be obtained.

On the other hand, clean or civilian cases have shown stumps functioning well for as long as 50 years of useful living with little handicap. These cases were operated upon before modern asepsis was developed, which makes the results more remarkable. Canadian surgeons are strong advocates of this procedure after following their World War I cases up to the present time.

The advantages of the procedure are several, but the main one is the preservation of a maximum amount of the extremity and full length leverage plus full end-bearing, with or without a prosthesis. It is possible for patients with even double Syme amputations to walk on the bare stumps in the house. With a prosthesis no apparatus extends above the knee, a particular advantage when a higher amputation exists on the other side. Syme amputees are not handicapped or incapacitated, merely inconvenienced. The bootlike prosthesis is fitted and maintained with relatively little trouble as compared with results following below-the-knee amputations, and function is excellent. When a partial foot amputation which will permit reasonably good function can be done, a Syme amputation should not be done in preference, but sound judgment must decide each case on its merits.

The only true disadvantage of the operation is esthetic, and therefore it is rarely done on a woman. For an adequate result, i.e., full painless end-bearing, the surgeon must meticulously carry out the surgery and personally conduct the aftercare until the patient is satisfactorily fitted with a prosthesis.

Indications are greatest among war injured in whom a functionally inadequate remnant of the foot is left. Open stumps must be clinically and bacteriologically clean, and edema must be at the irreducible minimum preoperatively. Split skin grafts may hasten the closure of old wounds, which is preferable before the Syme amputation is done. Cleanliness of the stump preoperatively is essential with bedrest and elevation of the stump. Penicillin given

preoperatively and postoperatively guards against activation of latent infection. Lumbar sympathectomy has preceded this operation when major venous ligation existed previously. Fractures of the lower tibia and fibula should be solidly healed as a prerequisite. All possible heel length is desirable, but with only a inch of heel a satisfactory Syme amputation can be done. If the heel remnant is fixed in equinus an advantage is obtained in that the skin is less redundant and less shrinkage occurs afterward. The skin of the heel must have good circulation and sensation, and be free from excessive scarring. When skin from the sole of the foot is not available for the stump, it is better to do a below-the-knee amputation and avoid disappointment.

The Syme amputation should never be a primary procedure on war casualties, not in the presence of nearby unclean wounds, loss of sensation, and peripheral vascular disease, with or without diabetes, are definite contraindications. Carefully selected cases of forefoot gangrene due to frostbite or trenchfoot have given satisfactory results.

FRANCIS F. HARNSECKER, M.D.

FRACTURES AND DISLOCATIONS

Higsmith, L.R. S., and Phalen, G. S.: Sideswipe Fractures. *Arch Surg*, 1915, 52, 313.

Fracture sustained with the left elbow projecting out of the window of a car which is sideswiped by an

oncoming vehicle is one of the most devastating injuries involving the elbow joint. The resulting injury is of such great magnitude that amputation is mandatory in about 50 per cent of the cases.

This fracture is a civilian casualty, and should be sufficiently publicized to impress the driver with the importance of keeping his arm inside the car while driving.

The authors report 7 cases of sideswipe fracture occurring among Army personnel. In 2 of the cases amputation was performed at the lower third of the humerus. In 2 other cases borderline amputations were done. In 3 of the cases nonunion of the humerus resulted at the supracondylar level.

The treatment consists of (1) debridement by sterile technique, (2) primary suture of the disrupted nerves, (3) cervical sympathetic block in all cases of vascular impairment, (4) extirpation of the loose bony fragments, (5) application of a cast from the axilla to the metacarpophalangeal joint, with the elbow flexed at a 90 degree angle, and (6) guinea pig amputation.

While some orthopedic surgeons have advocated immediate resection of the entire elbow joint, the authors lean toward conservative treatment. When extensive comminution of the bone exists, internal fixation—including wires, pins, and plates—is not the treatment of choice.

SIMUEL L. GOVERNILE, M.D.

Taske, L., and Shapiro, A. L.: Trimalleolar Fractures of the Ankle Joint. A Conservative Method of Treatment. *Am J. Surg*, 1915, 11, 613.

This report is based on a series of 31 trimalleolar fractures treated during a period of 5 years by the method described. The results were good from the functional standpoint in the 32 cases in which treatment was completed. Twelve of the patients were followed up for long periods.

The article discusses the history, anatomy, mechanics, and pathology involved in these injuries, and mentions the tendency of recent writers to recommend operative reduction. The method preferred by the authors is a 2 pin procedure using a mechanical distraction apparatus. The importance of accurate anatomic alignment of the fragments from the moment of reduction until union has taken place is stressed; it is difficult to achieve this in fractures in which one-third or more of the posterior articular surface of the tibia has been displaced.

The treatment varies according to the severity of the injury. First degree injuries, in which a small chip fracture of the lower posterior articulating surface of the tibia is detached and a partial displacement of the foot has occurred, are treated by manipulation, under either general or local anesthesia, and with the patient's knee and thigh flexed to relax the gastrocnemius muscles. Reduction is accomplished by downward traction, the foot being pulled anteriorly. The foot is dorsiflexed to 100 degrees and placed in slight inversion. This position is main-

Fig. 1. A, Anteroposterior, and B, lateral roentgenograms of left elbow taken 9 weeks following sideswipe fracture. There is little evidence of healing in the extensively comminuted humeral fracture.

tained by a boot length cast. No weight bearing is permitted for 8 weeks. Second degree injuries, in which a fragment comprising about one-third of the posterior articulating surface of the tibia is displaced and a subluxation of the astragalus is present, are manipulated as the first degree injuries, but when this fails, skeletal traction by means of a Kirschner wire or a Steinman pin is used. Sometimes a tenotomy of the tendo achillis is performed. The pins are placed in the middle third of the os calcis and in the tibia posterior to the tubercle. They are distracted by means of the MacMillan apparatus under observation with the fluoroscope. An assistant makes firm pressure on the shaft of the tibia as the foot is dorsiflexed. The traction is released when the astragalus is opposite the articulating surface of the tibia and the joint relationship is restored. In these cases the cast extends from the upper third of the thigh to the toes, the pins being incorporated in it. The foot is held at 100 degrees dorsiflexion and in inversion or eversion as required by the fractured malleoli. The pins remain in place from 10 days to 3 weeks or longer. Third degree injuries present complete dislocation of the foot. Their treatment is the same as that for second degree injuries, but often the tendo achillis must be tenotomized.

Postoperatively, one must watch for loosening of the cast. The pins should be left in place long enough to control the fragments despite the loosening of the cast.

NEWTON C. MEAD, M.D.

Lindsay, S., and Moon, H. D.: Bone-Marrow Embolism following Fracture. *J. Bone Surg.*, 1946, 28: 377.

When fat embolism of the lungs and brain occurs, it most often follows fractures of the shafts of the long bones. Such embolism occurs less frequently after fractures of the flat bones than after fractures of the ends of the long bones. Although 600 cases of fat embolism have been recorded in the literature, only 1 case of associated bone-marrow embolism to the lungs has been reported.

It seems probable that bone-marrow embolism occurs frequently after fractures. It would be necessary to examine the entire pulmonary tissue by microscopic sections in order to demonstrate the few fragments of marrow which have been liberated into the vascular system at the fracture site. The finding of such emboli in a few sections of pulmonary tissues is purely accidental. Three case reports are given in detail.

EMIL C. ROBITSHEK, M.D.

Soave, F.: The Intramedullary Nail Technique for Treating Fractures of the Long Bones, According to the Method of Kuentscher, and Its Indications (L'inchiodamento midollare delle ossa lunghe secondo Kuentscher, e sue indicazioni). *Arch. ital. chir.*, 1944, 66: 371.

The method of treatment of serious types of fracture, which was described by Kuentscher in 1941 under the designation of "Marknagelung," consists of the introduction of a long, relatively slender rod

Fig. 1.

Fig. 2.

Fig. 1. Instrumentarium for a femoral fracture: 1, extrator; 2, extracting hook; 3, mallet; 4, handle of guide; 5, bone punch; 6, guide; 7, intramedullary nail (Marknagel); and 8, extrator guide.

Fig. 2. Instrumentarium for a tibial fracture: 1, extrator; 2, extrator hook; 3, hammer; 4, bone punch; 5, double intramedullary nail; 6, protective circular band; 7, hand perforator; and 8, metric, metallic measuring instrument.

along the medullary canal of both the upper and lower fragments of the broken bone. This rod, or nail, which must be chosen to fit each case, is made of an alloy which is known as "V2A extra." Near one end of the bone an oblique hole is bored through the cortex into the medulla and the rod is driven into place under roentgen control after reduction of the fracture or pseudarthrosis. The intramedullary nail may be withdrawn with a special tool. (Figs. 1, 2).

The author treated 3 cases of old, deformed, non-union fractures (1 of the left leg, 2 of the right forearm, and 1 of the left forearm) with this technique and asserted that these were the first 3 cases so treated in Italy. The results obtained were excellent. The limb did not require other support while it healed, the period of treatment in the hospital was very much shortened; and there was no evidence in any instance of infection or interference with the development of callus. In each case, when the nail was extracted, it was as smooth and as highly polished as when it was introduced.

JONAS W. BIRNBAUM, M.D.

ORTHOPEDICS IN GENERAL

Regan, J. M., and Chatterton, C. G.: Deformities following Surgical Epiphyseal Arrest. *J Bone Surg*, 1946, 28, 255.

This report includes all surgical epiphyseal arrests performed at the Gillette State Hospital from June 1, 1933 to December 31, 1943, inclusive, which afforded a postoperative checkup of at least a year to December 31, 1944. During this period of 10 years and 7 months, a total of 36 patients underwent operation for epiphyseal arrest for inequalities of leg length. The etiologic factors for the discrepancies of leg length in this series seemed to coincide with the findings of most writers. Tabulations were made including the sex, epiphyses arrested, age at time of operation, amount of discrepancy in length of legs at the time of operation and at the time of follow-up, and length at the time of the follow-up. In some instances equalization did not occur, yet the procedure arrested progressive discrepancy. It is interesting to note that deformities following arrest and directly attributable to the procedure occurred only in males in this series; this fact, of course, is of no significance in determining the outcome of the operation.

The technique of Phemister was followed in all cases, with only slight modifications, depending on the individual surgeon performing the operation.

Of the 36 patients, 4 showed noticeable deformity in from 2 months to 2½ years after arrest had been effected. In 3 of these cases corrective surgical procedures were performed after the deformity occurred and in 2 of these re-arrest of the epiphyses was performed at the time the corrective operation was done. In the fourth case the authors contend late corrective osteotomy if the deformity increases.

Blaine, G.: Experimental Observations on the Use of Absorbable and Nonabsorbable Plastics in Bone Surgery. *Brit. J. Surg*, 1945, 33, 215.

Experimental investigations were made of non-protein and protein plastics. Of the nonprotein plastics the following were studied: methyl methacrylate, cellulose acetate, nylon, urea and phenol. Methyl methacrylate proved most satisfactory.

The protein plastics studied were made from casein, fibrin, casein with plasma, red blood cells, and whole blood. The protein plastic chiefly studied was casein plastic.

A detailed description of the preparation of casein plastic is given. This plastic is placed in a formalin bath (4 per cent), which penetrates about 1 mm. in 14 days, this makes it 30 per cent stronger, and eliminates the element of putrefaction. These plastics can be machined to provide screws, plates, blocks, and nails. The strength of these plastics is approximately that of bone. The strength increases with greater formalization, and decreases if stored under unsatisfactory conditions.

Protein plastics are completely absorbed by the tissues. The speed of absorption depends on: (1) the degree of formalization, (2) the bulk of the implant, and (3) the tissue in which it is placed. Absorption is faster in bone than in skeletal muscle.

Nonprotein plastics are not absorbed in the soft tissues or in bone. Methyl methacrylate is well tolerated by the tissues and often produces little or no fibrous reaction. Methods of rapid molding of acrylic sheets make this plastic more useful in bone surgery in the primary operative procedure.

DANIEL H. LEVENTHAL, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Blakemore, A. H.: Angiography—An Evaluation of Its Usefulness. *Surg. Clin. N. America*, 1946, 26: 326.

In this article, the author discusses some of the outstanding benefits of angiography. Because of their relatively low toxicity and rapid elimination the iodides are favored as contrast media for the x-ray visualization of the vascular system. Of the group, diodrast is a popular compound in America.

It is indeed a compliment to the many contributors to angiography to state that in a short number of years, since its beginning, it has become possible to obtain excellent pictures of any portion of the human vascular system. Techniques have been evolved which make the safety of angiography in any region entirely commensurate with its diagnostic importance in given instances. This implies that cerebral angiography should not be employed on the slightest provocation, but it does mean that when there is a question of serious doubt in diagnosis the cerebral vessels can be visualized safely to rule out, for example, the presence of an arterial aneurysm. Angiography of the vessels of the head has been employed to localize more accurately the site of a traumatic arteriovenous fistula. In cases of congenital arteriovenous aneurysm of the cerebral vessels important information may regularly be gained from angiography.

The method of aortography is discussed in detail. The right common carotid artery has been used for retrograde visualization of the arch of the aorta by means of a long, flexible needle with a tapered blunt stylet. Visualization in sequence by x-ray of the superior vena cava, the heart chambers, the pulmonary vessels, the aorta, and its branches following the rapid introduction of 70 per cent diodrast in an arm vein represents a truly great achievement in angiography. In cardiovascular disease, this method of contrast roentgenography has given a degree of precision in diagnosis previously unattainable. It may aid in the diagnosis and treatment of the various types of mediastinal disease. The most striking results are obtained, however, in disorders such as aneurysm of the pulmonary artery, aortic disease, and pericardial and congenital abnormalities in which recognition is difficult or impossible with conventional methods of study. Whereas the technique of carrying out serial contrast roentgenography following opacification is exacting, proficiency in the procedure can be readily acquired through training and practice, and successful performance should be within the capability of every medical center.

The author states that arteriography of arteriosclerotic peripheral arteries should not be dismissed without a word of caution. It should be remembered that all the radiopaque substances employed in

angiography are irritating to the vessel wall, some more than others. Although it may be claimed that the irritation is insufficient to cause enough direct damage to the intima to serve as a localizing focus for the initiation of a thrombus, the substances all do cause vasospasm. The latter may, in the presence of arteriosclerotic intimal plaques, be just sufficient to initiate thrombosis in the distal branches of the artery.

Some observers in the early days of angiography suggested the method as an aid in revealing the adequacy of collateral branches around areas of obstruction. Arteriography for this purpose is dangerous and, furthermore, because of the superimposed vasospasm, it is not particularly informative. Perhaps the most informative and certainly the most interesting application of angiography is in cases of arteriovenous fistula, congenital or acquired. Whereas in congenital fistulas, which are almost invariably multiple, the angiogram may not always show up the actual fistulas, it is sufficiently localizing to be an important guide to surgical therapy.

The case of an 11 year old boy with an overgrowth of the leg is presented and discussed in detail. The exact explanation of overgrowth of the extremities in children having arteriovenous fistula is not known. The skin temperature difference between the normal and affected limb may be marked. The simplest proof of this is exhibited during ether anesthesia. At the start of the anesthetic the affected limb will be warmer, but after a third stage anesthesia is reached the temperature in the normal and affected limb becomes equalized. It is probable that the diminished vasomotor tone in the limb affected by arteriovenous fistula is chemical in origin, perhaps due to an increased carbon dioxide content.

Overgrowth of the bones and soft parts are the most distressing features of arteriovenous fistula in children. Bone overgrowth is not of great concern, however, because it simply means that the epiphyses will close earlier in the affected member and in time the bone growth in the normal limb will catch up. For this reason the author states that he is not in favor of operating upon the epiphyses. And for the same and other reasons he is against the use of x-ray treatment. Excision of the fistulas is the ideal therapy.

The role of angiography in arterial anastomosis is discussed in detail. Arteriograms are not necessary to determine the patency of anastomoses in clinical cases that have been carefully followed. Arteriography shows whether a given anastomosis is patent or not, however, and is useful as a photographic record which may be employed in testing the efficacy of a given technique of blood vessel anastomosis. Arteriography was employed in testing the efficacy of a nonsuture method of blood vessel anastomosis with vitallium tubes.

The author states that there are occasions in which venography is extremely useful. Its greatest usefulness is in determining the adequacy of the deep venous system of the leg in old postphlebotic cases. In such cases it may be desirable to strip the great saphenous vein because of varicosities, or to do a flap dissection for ligation of the perforating branches.

HENRY F. THURSTON, M.D.

DeBakey, M. E., and Simeone, F. A.: *Battle Injuries of the Arteries in World War II. Ann. Surg.*, 1946, 123: 534.

The incidence of vascular injuries in World War I has been 0.06 per cent of all wounds in the American Army. Vascular injury was the cause for 0.5 per cent of the amputations. The therapy of vascular wounds has been limited by the time lag which is unavoidable in military surgery. In most cases the treatment was complicated by injuries to structures other than the blood vessels, e.g., bones, nerves, and muscles. The incidence of amputation was appreciably higher in the cases in which vascular injuries were complicated by fractures. On the basis of the American experience in World War II, as well as the British experience in World War I, it is apparent that the site and type of the vascular wound determined the therapeutic procedure and, therefore, predetermined the end results. Thus a wound of the popliteal artery was much more likely to be followed by ischemic gangrene than a laceration of the brachial artery. The great majority of the wounds in World War II were produced by shell fragments; they were large and were associated with extensive destruction of tissue, hence frequently they resulted in the loss of much of the potential collateral circulation. As a result the vitality of the limbs was gravely impaired before the surgeons ever saw most of the patients. Infection was not a common complication.

Of necessity, the most common type of treatment of wounded arteries was ligation. The incidence of gangrene was higher than that reported by Makins in World War I; the difference was attributed to the exclusion of chronic cases, such as arteriovenous aneurysms, from the American Army series. Despite the evidence previously adduced by various authors to demonstrate the value of concomitant venous ligation, the incidence of amputation when the vein was ligated along with the artery was not appreciably lower than when the artery alone was ligated.

Repair by suture was rarely possible because of the time required and the extensive wounds that were usually encountered, with widespread destruction of tissue and such loss of arterial substance that end-to-end anastomosis was rarely feasible. Only 81 cases were treated by suture and most of these were small lateral lacerations, involving a third or less of the circumference of the vessel. The incidence of amputation in this group was 35.8 per cent, not strikingly better than the figure of 48.9 per cent in the group treated by simple ligation.

Forty patients had nonsuture repair with vein grafting according to the technique of Blakemore

and Lord. The incidence of amputation was highest in this series (57.5%), and the procedure was found to be very time-consuming. An anastomosis was performed with a plastic tube in 14 cases, half of which were subsequently subjected to amputation.

Anticoagulant therapy was rarely employed as a supplemental therapeutic measure because of the time lapse from the injury to the first definitive treatment, because of the frequent presence of other injuries, and because of the difficulties of control by means of evacuation. Sympathetic block with procaine was performed frequently, but in the material available for analysis it was possible in only 278 cases to determine definitely that the procedure had been performed or had been omitted. The incidence of amputation was 30.3 per cent in the patients who had received blocks, and 48.8 per cent in those who had not. In 42 cases sympathectomy was done, with subsequent amputation in 71.4 per cent. The latter was probably necessary because of the fact that the sympathectomy was used generally only as a last resort. Despite their lack of statistical evidence, the authors are convinced that both sympathetic block and ganglionectomy are of considerable value after arterial injury. Fasciotomy to relieve pressure on ischemic muscles in tight fascial compartments was used in only a few American cases. The results were good occasionally except in patients with wounds of the popliteal artery, and in the majority of these the results were poor. Refrigeration was not considered practical under combat conditions.

The complications and sequelae included secondary hemorrhage only rarely, and gas gangrene in 11 per cent of all amputations. No statistics were available on the incidence of causalgia, but it was noted to be higher when there were associated nerve injuries. A great many of the patients suffered from various manifestations of circulatory insufficiency, such as color changes, intermittent claudication, and even partial paralysis. Most of these conditions improved after sympathectomy. The treatment of ischemic contractures has been less satisfactory.

THEODORE B. MASSELL, M.D.

Ogden, E., and Sherman, R. S.: *Physiologic Considerations in the Care of Patients with Varicose Veins. Arch. Surg.*, 1946, 52: 402.

Considered from a physiologic point of view, the chief features of all varicose conditions are (1) valvular incompetence, (2) raised venous pressure, and (3) edema. Congenital inadequacy in one or more pairs of venous valves at the upper end of the long saphenous system begins with mild incompetence during the preadolescent years, and progresses into generalized venous breakdown which is accelerated or precipitated by pelvic congestion, by any factor raising intra-abdominal pressure, by prolonged standing, or by occupations which involve repeated straining. The upper valves failing, the column of blood sustained by the lower valves becomes longer and therefore heavier, which causes the veins to give

way. This increased tension produces (1) a thickening of the muscular coat of the larger vessels so that they feel straight, thick, and firm, and (b) tortuosity, reverse flow of blood in the smaller vessels. A blood flowing downward and entering the deep veins via perforating vessels and then ascending and flowing back through the saphenofemoral junction or through the perforating vessels up in the thigh. Raised venous pressure and stagnant anoxia occur, which combine to upset the balance of turnover of the tissue and produce edema; this stagnant tissue fluid leads to the formation of fibrous tissue, discoloration of the skin, and ulcers.

In varicose veins without complications, a complete personal and occupational history, as well as an evaluation of the development of signs and symptoms, is of value for determining the prognosis of the varicose condition and the probability of recurrence after treatment. Life expectancy of the patient, evidence of arterial inadequacy, and previous treatment are a few of the important factors to be weighed before physical examination and treatment are carried out.

In the examination the following factors should be noted: (1) the size and tension of the visible veins and the presence of varices; (2) the presence of reverse flow in the long saphenous vein, also the thickness of the wall of this vein; (3) evidence of deficiency in the arterial circulation as manifested by color and temperature changes, and the presence of arterial pulsations; (4) the presence of deformities or orthostatic defects in the feet; (5) the presence of pain, which usually is an indication of thrombophlebitis; (6) the presence of ulcers, dermatitis, edema, telangiectasis, or pigmentation; and (7) the presence of fungus infection. Reverse flow in the perforating veins below the knee is best determined by rapid filling time of the veins when a tourniquet is applied below the knee; the incompetent communicating valves thus revealed are a poor prognostic sign, and the patient at best may expect to have trouble more or less during the rest of his life. If there is no venous incompetence below the knee, incompetence at the place where the short saphenous vein perforates the fascia into the popliteal space may be determined by observation of rapid reverse filling of the saphenous vein when a tourniquet is applied above the knee. Major valvular incompetence somewhere in the thigh may be determined by rapid filling of the saphenous vein when a tourniquet is applied high up on the thigh below the saphenofemoral opening. Finally, incompetency of the valves of the long saphenofemoral opening may be determined by rapid filling of the vein when a tourniquet placed at the top of the thigh is released.

The aim of all treatments of uncomplicated varicose veins is the elimination of back pressure on the capillaries, which indicates a backward flow through an incompletely guarded communication between the superficial and deep venous systems—the elimination of all perforating vessels with incompetent

valves is the logical treatment. This is straightforward when incompetence occurs at the saphenofemoral opening, the so-called "high saphenous ligation," but it is important that enough of the femoral tributaries are above the point at which the saphenous vein has been tied; if any are present they should be tied, cut, and removed. The stump of the vein should be tied as closely as possible to the femoral vein and 5 cm. of the vein should be excised. A sclerosing solution may be injected distally into the main trunk of the saphenous vein. Full activity of the limb may be tolerated within a few days. Recurrence of the symptoms following operation may be due to (1) too low a ligation, or (2) failure to visualize the femoral vein and ligate all its upper branches; recanalization of the saphenous vein by reverse flow through incompetent valves in the perforating vessels may also occur.

As it is often difficult to isolate and tie off all these vessels, Sherman's stripping procedure, which is designed to interrupt the perforating vessels, may be carried out at the same time as the high ligation. This procedure, done with a vein stripper which is passed down the length of the thigh and part of the leg, is designed to explore the pattern taken by the saphenous vein and to avulse all parts of it which might communicate with the deep system. After a sclerosing solution is injected into the vein, it is then nicked at various points and inspected for bleeding.

Many surgeons who believe that this procedure is too radical advocate a simultaneous high and low ligation of the internal saphenous vein.

The injection of sclerosing solution alone, usually followed by recanalization, is useful only in certain conditions: for instance, (1) in treating trifling varices for a cosmetic effect; (2) when surgical treatment is contraindicated; (3) when operation must be deferred; (4) when surgery is refused; (5) during pregnancy; (6) when supplemental treatment to surgery is desired to obliterate persistently distended veins; and (7) when incompetent veins below the knee limit the success of the operative procedure. Incompetent perforating veins below the knee cannot, as a rule, be successfully ligated, mainly because they are multiple and of uncertain location; in these cases a high ligation and local sclerosing injections should be employed.

The outstanding complications of varicose veins are (1) dermatitis, (2) edema, (3) varicose ulcer, and (4) thrombophlebitis. Dermatitis and itching are due chiefly to fungus infection; control of the edema which allows the fungus to thrive is the prime treatment, although various local medicaments, such as 5 or 10 per cent silver nitrate in 50 per cent alcohol or a hot strong solution of magnesium sulfate, give relief. High saphenous ligation usually brings about resolution of the dermatitis, although caution must be observed that the infection does not invade the operative site. Uncomplicated edema is controlled by rest with the feet elevated and tight bandaging. An effective although intricate pressure bandage is

The author states that there are occasions in which venography is extremely useful. Its greatest usefulness is in determining the adequacy of the deep venous system of the leg in old postphlebotic cases. In such cases it may be desirable to strip the great saphenous vein because of varicosities, or to do a flap dissection for ligation of the perforating branches.

HERBERT F. THURSTON, M.D.

DeBakey, M. E., and Simeone, F. A.: *Battle Injuries of the Arteries in World War II. Ann. Surg.*, 1946, 123: 534.

The incidence of vascular injuries in World War II has been 0.6 per cent of all wounds in the American Army. Vascular injury was the cause for 19.5 per cent of the amputations. Finally, incompetency of the valves of the long saphenofemoral opening may be determined by rapid filling of the vein when a tourniquet placed at the top of the thigh is released.

The aim of all treatments of uncomplicated varicose veins is the elimination of back pressure on the capillaries, which indicates a backward flow through an incompletely guarded communication between the superficial and deep venous systems—the elimination of all perforating vessels with incompetent

valves is the logical treatment. This is straightforward when incompetence occurs at the saphenofemoral opening, the so-called "high saphenous ligation," but it is important that enough of the femoral vein be thoroughly exposed to make sure that no tributaries are above the point at which the saphenous vein has been tied; if any are present they should be tied, cut, and removed. The stump of the vein should be tied as closely as possible to the femoral vein and 5 cm. of the vein should be excised. A sclerosing solution may be injected distally into the main trunk of the saphenous vein. Full activity of the limb may be tolerated within a few days. Recurrence of the symptoms following operation may be due to (1) too low a ligation, or (2) failure to visualize the femoral vein and ligate all its upper branches; recanalization of the saphenous vein by reverse flow through incompetent valves in the perforating vessels may also occur.

As it is often difficult to isolate and tie off all these vessels, Sherman's stripping procedure, which is designed to interrupt the perforating vessels, may be carried out at the same time as the high ligation. This procedure, done with a vein stripper which is passed down the length of the thigh and part of the leg, is designed to explore the pattern taken by the saphenous vein and to avulse all parts of it which might communicate with the deep system. After a sclerosing solution is injected into the vein, it is then nicked at various points and inspected for bleeding.

Many surgeons who believe that this procedure is too radical advocate a simultaneous high and low ligation of the internal saphenous vein.

The injection of sclerosing solution alone, usually followed by recanalization, is useful only in certain conditions: for instance, (1) in treating trifling varices for a cosmetic effect; (2) when surgical treatment is contraindicated; (3) when operation must be deferred; (4) when surgery is refused; (5) during pregnancy; (6) when supplemental treatment to surgery is desired to obliterate persistently distended veins; and (7) when incompetent veins below the knee limit the success of the operative procedure. Incompetent perforating veins below the knee cannot, as a rule, be successfully ligated, mainly because they are multiple and of uncertain location; in these cases a high ligation and local sclerosing injections should be employed.

The outstanding complications of varicose veins are (1) dermatitis, (2) edema, (3) varicose ulcer, and (4) thrombophlebitis. Dermatitis and itching are due chiefly to fungus infection; control of the edema which allows the fungus to thrive is the prime treatment, although various local medicaments, such as 5 or 10 per cent silver nitrate in 50 per cent alcohol or a hot strong solution of magnesium sulfate, give relief. High saphenous ligation usually brings about resolution of the dermatitis, although caution must be observed that the infection does not invade the operative site. Uncomplicated edema is controlled by rest with the feet elevated and tight bandaging. An effective although intricate pressure bandage is

described; it consists of a layer of sheet wadding placed over the skin (previously covered with tincture of benzoin), close fitting rubber sponges on each side of the leg, gauze bandages, and adhesive tape applied like a puttee. This bandage is left on a week and then another is applied. The degree of tightness depends on the status of the arterial circulation. When edema is thus eliminated a well fitting elastic stocking may be employed. True varicose ulcers heal spontaneously and rapidly in the absence of edema, venous back flow, or vascular insufficiency. Rest and elevation of the feet usually suffice, although healing may be facilitated by the application of silver nitrate solution and the pressure dressing mentioned previously. A painful inflamed ulcer is treated in a similar manner, codeine and salicylates being used during the first day or two that the bandage is in place; when the edema is eliminated the ulcer clears.

Thrombophlebitis may be divided into three categories: (1) low grade superficial thrombophlebitis; (2) progressive superficial thrombophlebitis; and (3) femoral thrombophlebitis. In the first group, soreness and bruising of superficial varicose veins are the chief complaints; the disease is generally self limited and requires no particular therapy. Extensive superficial varices often are the site of a rapidly progressing superficial thrombophlebitis (this is seen especially in pregnancy); the region is tender and inflamed, it may spread to the saphenofemoral opening, but the femoral system is rarely invaded and emboli are seldom produced. It is of prime importance, however, to distinguish this condition from deep femoral thrombophlebitis. Since there is no particular hazard connected with superficial thrombophlebitis, symptomatic measures usually suffice (rest, narcotics, warm or cold applications), although ligation of the saphenous vein at the saphenous opening may be carried out with more rapid resolution of the symptoms. This condition is frequently the forerunner of an ulcer.

Deep femoral thrombophlebitis is a true hazard to life because of the danger of emboli. It is usually heralded by pain, tenderness, swelling of the thigh and leg, and signs of infection (elevation of temperature), and immediate measures should be taken to combat it, such as (1) immediate ligation of the femoral vein below the junction of the profunda femoris and removal of the clot by aspiration; (2) sympathetic block; (3) rest and elevation; and (4) employment of heparin or dicoumarin. The best prophylactic measure against deep thrombophlebitis is that the patient keep his legs active while in bed.

The bearing of this condition on a discussion of varicose veins lies in the overtaxing of the superficial venous system and the production of varicosities when the deep system is obstructed. When this occurs, the development of superficial varicosities should be anticipated and forestalled, or at least delayed. Rest and elevation should be enforced until all edema has disappeared. When the danger of embolism is passed, blood flow should be promoted

by warmth, massage, and active movement. The use of an elastic bandage or stocking is advocated, and the patient is to be warned against (1) walking without support; (2) pregnancy; (3) straining or lifting; and (4) constipation. Signs of growing valvular incompetence should be watched for. No surgery should be attempted on the long saphenous system until the deep femoral system has been demonstrably recanalized and is capable of carrying the whole venous return; a year should elapse prior to surgery to allow for subsidence of a possibly dormant infection. Complete cure is seldom effected, and no false hopes should be held out to the patient.

BLOOD; TRANSFUSION

Rosenthal, N., Zimmerman, S. P., and Shapiro, S.: The Prothrombin Level of the Peripheral Blood and the Sternal Marrow. *Arch. Int. M.*, 1946, 77: 420.

Although much is known about the properties of prothrombin, little is known of its metabolic cycle. Conclusive evidence is lacking that the liver is the major or sole locus for its synthesis. Prothrombinopenia accompanies artificially induced or clinical hepatocellular damage and thus it has been felt that the liver plays an important role. Which of the components, the parenchymatous or the reticuloendothelial cells, performs the action has not been determined. Little is known, also, of the manner in which vitamin K and dicoumarin exert their influences on the prothrombin levels.

In an attempt to determine whether a relationship could be found in the production of prothrombin between the reticuloendothelial activity and function presumably of the liver, the authors took an indirect approach. A comparison was made of the prothrombin clotting time of plasma obtained simultaneously from the peripheral venous blood and from the sternal bone marrow.

Studies were made on whole and diluted plasma (12.5 per cent). Twenty-eight normal patients were studied and it was established that there was no significant difference between the prothrombin level of the peripheral blood and that of the bone marrow. From this it was concluded that the reticuloendothelial system is not involved in the production of prothrombin.

Next, 8 patients were given large doses of quinone and no difference was found between the marrow and peripheral plasma, each showing a similar decrease in the prothrombin time. Thus, during a period of rapidly increasing production of prothrombin there was no difference between the peripheral and plasma marrow. This added support to the contention that the bone marrow and the reticuloendothelial system are uninvolved in the metabolism of prothrombin.

A third series of studies was made on 7 patients who were given significant doses of dicoumarin 48 hours before the samples of blood were taken. A prolongation of the prothrombin time with a dissocia-

tion of the effect on the peripheral and marrow plasma was found, the latter showing a relatively greater prolongation. It was reasoned that dicoumarin serves to hasten the process of destruction of prothrombin and that this is probably done by the reticuloendothelial system.

Studies on 5 patients receiving simultaneous doses of dicoumarin and quinone yielded results similar to those in patients receiving dicoumarin alone. It is concluded that the effects of quinone and dicoumarin are opposite but that they are not directly antagonistic. Dicoumarin probably produces the effect not only by the prohibition of the formation of prothrombin but also by facilitating its destruction. Thus, despite vitamin K therapy the bone marrow plasma contained a decreased amount of prothrombin as compared to peripheral plasma. This was probably due to active destruction of the prothrombin by the reticuloendothelium of the marrow.

The author arrives at the following conclusions:

1. Prothrombin is not produced by the reticuloendothelial system and therefore such production is not a function of the hepatic parenchyma.
2. Prothrombin is equally distributed in the sternal marrow and in the peripheral blood stream.
3. Vitamin K accelerates the production of prothrombin, and the excess which results is equally distributed in the marrow and the peripheral blood.
4. Dicoumarin causes a more pronounced decrease in prothrombin of the marrow than in the peripheral blood stream. The evidence is suggestive that this is due to the destruction of prothrombin, most likely by the reticuloendothelial system.
5. When dicoumarin is given simultaneously with synthetic vitamin K, even if the former is in relatively small amounts and the latter in massive quantities, the action of the dicoumarin usually predominates.

EDMUND R. DONOGHUE, M.D.

Watson, C. J.: Some Newer Concepts of the Natural Derivatives of Hemoglobin. *Blood, J. Hemat.*, 1946, 1: 99.

The author states that protoporphyrin is the underlying porphyrin of the hemoglobin molecule. The name simply indicates that protoporphyrin is a representative or prototype of the various naturally occurring porphyrins insofar as its widespread occurrence and physiological significance are concerned. Protoporphyrin is the substance which binds the iron of the hemoglobin molecule. This was first established by the studies of Kammerer and others. The underlying porphyrin of the hemoglobin molecule is hemaporphyrin. The latter substance is formed when hemoglobin is treated with concentrated sulfuric acid, but it is an artificial compound not occurring naturally.

It has been an important question in the past as to whether protoporphyrin is intermediate in the pathway between hemoglobin and the bile pigments. It was formerly believed, probably because of the care with which hematin is formed in vitro by the treatment of hemoglobin with either acid or alkali, that

hematin, a ferric complex of protoporphyrin, was the first step in the transition to bile pigment. In recent years, Hamilton Fairley has shown that hematin is bound to some portion of the albumin fraction of the plasma protein when it is present in the circulating plasma in pathological states such as, for example, blackwater fever, severe liver disease, gas bacillus sepsis, and other conditions. The author notes that globin has approximately the same molecular weight and the same electrophoretic behavior as albumin, so that a hematin formed under natural conditions and still attached to globin would be expected to be associated with the albumin fraction. The term, methemalbumin, is used to designate this association. There is no reason to believe, however, that hematin or methemalbumin is a normal intermediary substance in the transition of hemoglobin to bilirubin.

In his summary and conclusions, the author states that the transition of hemoglobin to bile pigment, at least under normal conditions, is believed to occur via an intermediate biliverdin-globin-iron (verdo-hemoglobin) and not over the stages of hematin and protoporphyrin. It is probable that the next step is a reduction to bilirubin with a splitting off of iron. There is much reason to believe that the globin remains attached until the bilirubin passes through the liver cell, the bilirubin globin exhibiting a delayed or indirect van den Bergh reaction and not being excreted in the urine, and the sodium bilirubinate of the bile exhibiting a prompt (I') van den Bergh reaction and being readily excreted in the urine. The former type is characteristic of retention, the latter of regurgitation jaundice.

Bilirubin which is attached to its original globin is responsible for the delayed or indirect van den Bergh reaction. It may be due to the fact that bile is weakly alkaline, and it is not unlikely that the bilirubin in the bile is the sodium salt.

The appearance of bilirubin in the urine is believed to be related to the concentration in the blood of the I' or prompt bilirubin, rather than that of the total bilirubin. It is evident that the threshold may be considerably lower at the onset of jaundice, as, for example, in hepatitis, than during its defervescence. This undoubtedly accounts for the appearance of bilirubinuria prior to recognizable jaundice in certain instances, likewise for its presence in the cases of so called "hepatitis without jaundice." In retention jaundice, marked elevation of the total serum bilirubin is unassociated with bilirubinuria; in these cases the increase of bilirubin is mainly of the delayed or indirect reacting type. Further evidence is presented of the essential difference between the I' (or prompt) and the T minus I' (or delayed and indirect reacting) bilirubins. This consists of a change of the order of reaction at one minute after adding the diazonium salt. The normal upper limit of the I' bilirubin has been shown to be around 0.2 mgm. per 100 c.c.; figures well below this value are usually obtained.

Further experience with the erythrocyte protoporphyrin in the anemias has revealed that this determination, quite apart from its fundamental

interest, is at times of diagnostic value. Thus, in several instances a significant elevation of the erythrocyte protoporphyrin has indicated that the initial impression of pernicious anemia was incorrect, and has led to the search for other information. Conversely, a low normal value in the presence of anemia has often correctly indicated or confirmed the diagnosis of pernicious anemia. Marked elevations have aided in confirming the presence of iron deficiency and have given some insight into the degree of its severity and chronicity.

In conclusion the author states that in certain cases, high values for the erythrocyte protoporphyrin have suggested the possibility of heavy metal toxicity, the existence of which has been borne out by subsequent study. **HEARNFAT F. THURSTON, M.D.**

Capovani, L.: Alterations in Normal and Decapsulated Kidneys Caused by the Transfusion of Heterogenous Blood (Le alterazioni da trasfusione di sangue eterogeneo puro nei reni normali e nei reni decapsulati). *Arch. ital. chir.*, 1944, 66: 205.

The author transfused human blood into rabbits and studied the resulting changes in decapsulated

kidneys and in corresponding normal organs. In animals with intact kidneys he found alterations of the renal function in the form of anuria, oliguria, hemoglobinuria, cylindruria, and diminished excretion of urea.

The anatomopathological examination disclosed a degenerative nephropathy. The histological studies showed degenerative changes of the tubular epithelium, dilatation and infiltration of a part of the excretory tubuli, and the presence of hyaline and granular casts and exfoliated epithelium. The author assumes that such changes are caused by a toxic substance deriving from the plasma and disintegrated morphologic structures of the blood which has been transfused.

The decapsulated kidneys were larger and more voluminous than the intact kidneys, and the histological examination showed a more pronounced infiltration of the excretory system and more numerous hyaline casts as compared with the intact kidneys. The greater intensity of the lesions is probably caused by local changes which take place in the circulation in the decapsulated kidneys.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Conway, H., and Coldwater, K. B.: *Principles in Reparatve Plastic Surgery. Surgery, 1946, 19: 437.*

Problems in plastic surgery encountered in the Philippine campaign between October, 1944 to March, 1945 are discussed.

Transportation problems in vast Pacific distances influenced greatly the choice of procedure. Forty-nine per cent of the patients were seen in from 5 to 8 days after injury in this campaign, and 36 per cent were seen in from 21 to 55 days following injury in another campaign.

The authors discuss 468 secondary closures, 305 split-skin grafts, 46 small deep grafts, and 28 primary procedures involving the transplantation of flaps of skin and subcutaneous tissue. The final reconstructive surgery, of course, was to be done at a later time, the main consideration in this theater being one of either having the patient return to duty early, or treating him so as to minimize the transportation hazard while being sent to plastic centers in the United States.

Wounds which had been treated with frequent change of dressings were in far better condition than those which had been treated by the closed method. *Bacillus proteus*, *bacillus pyocyaneus*, and *staphylococcus* were the common contaminants. *Streptococci* were rarely found. In a series of 4,040 battle casualties, *clostridium welchii* were found in 37 cases.

Preoperative treatment consisted of wet dressings of a 1:3300 aqueous solution of azochloramid. These were changed at four hour intervals after preliminary removal of necrotic tissue. Occasional dermatitis resulting from this was treated with a mild astringent. The local application of penicillin was found to be a useless extravagance. In fact, penicillin dressings were followed by a striking increase in wound exudate and in the growth of gram negative organisms. Sulfonamide drugs were not used locally in wounds. Systematic administration of sulfadiazine or penicillin was limited to patients who were febrile or toxic, or whose wounds showed streptococci or evidence of spreading infection.

In the choice of operative procedure, secondary suture, whenever possible, unquestionably was the best method of closing war wounds, although unhealed wounds over 4 weeks of age were less suitable for closure. Secondary closures were contraindicated in the region of the elbow, the distal third of the forearm, and in the hand. Similar closure of wounds in the regions of the groin, knee, distal third of the leg, ankle, and foot was not likely to succeed.

Of the secondary closures, 85.7 per cent of the wounds healed completely, 7.6 per cent had partial

separation, and 6.7 per cent had complete failure. Pressure dressings were applied, and extremities were immobilized and elevated. Failures resulted from undue tension, or attempts to obtain cosmetic results with suture. Such procedures should never be used when the skin and fat at the margins of the wound are indurated.

Split thickness grafts were used in the treatment of 306 patients, with 86.6 per cent completely healing; 6.9 per cent were a partial failure, and 6.5 per cent, complete failure. In the vast majority of cases free split thickness grafts were used, and open dressings of fine mesh gauze covered with collodion. Saline dressings were applied and changed at four-hour intervals. The extremities were generally immobilized in plaster with a window at the operative site. Immobilization was discontinued in from the ninth to the twelfth day, and a pressure dressing substituted. Where plaster fixation was not feasible, skeletal or adhesive traction immobilization was found valuable.

The causes of failure were for the most part due to errors in surgical judgment, in the proper selection of the optimum time for surgery, and in the technique of postoperative care.

Small deep grafts approximately 0.7 cm. in diameter, closely placed, were thought very valuable in the covering of certain lesions in the groin, popliteal area, antecubital fossa, and over certain bony prominences. Pedicle flaps and temporary split grafts could be used only infrequently in the treatment of wounded soldiers at the time the authors had them under their care. LOUIS T. BYARS, M.D.

Greeley, P. W.: *The Plastic Correction of Superficial Vascular and Pigmented Nevi. Surgery, 1946, 19: 467.*

The author discusses the correction of vascular oevi, which he divides into the capillary and cavernous types. Each type may be found anywhere and may be of any size. The etiology is unknown. The treatment formerly consisted of carbon dioxide snow, radium, or x-ray, which even now functions well in simple lesions; but in the more complicated group excision should be carried out with closure of the defect, or the application of a properly selected skin graft. In some cases in which the defect is very large and closure is elected, this may be done in multiple stages.

The cavernous type of oevi occasionally progresses with age so that early treatment is the procedure of choice. Rupture and hemorrhage can result from oeglect, as can chronic infection. These angiomas are best treated by surgical excision but oftentimes such treatment should be preceded by the injection of sclerosing fluids, partial ligation, or exposure to x-ray or radium, the thought being that the danger of hemorrhage can be minimized because of the

fibrosis which will result. As in the case of capillary nevi, these defects can be closed either by primary suture or by the application of skin grafts, or adjacent skin flaps.

Pigmented nevi are brownish colored lesions varying in shade from café au lait to deeper brown colors. The darker shades of nevi are more likely to take on malignant changes, whereas the large brownish growths, contrary to popular belief, seem to become malignant very rarely. The etiology has not been solved.

For the sake of safety, expediency, and the best cosmetic results, pigmented nevi should be excised, the deep brown colored nevi being excised widely and the adjacent skin edges closed. The larger tumors may be removed by excision and closure either in single or multiple stages, or by the use of a properly selected skin graft.

The author presents 17 cases which illustrate the various points mentioned in his article.

LOUIS T. BYARS, M.D.

Shaw, D. T., and Payne, R. L., Jr.: Repair of Surface Defects of the Upper Extremity. *Ann. Surg.* 1946, 123: 705.

The selection of the proper type of replacement for surface defects of the upper extremity is dependent upon the amount and degree of tissue loss. Ifence a procedure may be as simple as a scar excision or as extensive as a pedicle graft. Scar excision and the removal of foreign bodies, nonvital bone, and irreparably damaged tendon should be done at the time of replacement. Elevation of the extremity and mild pressure dressings are recommended for the prevention of edema and fibrosis. The hand and arm are splinted in the position of function. If damaged and denervated muscles are involved, a neutral position is maintained to prevent contracture. An open wound should be eliminated whenever possible even if it requires a thin split graft as a temporary dressing. Graft margins should be placed in conformity with Langer's lines.

The ideal method in the repair of surface defects is excision of scar tissue and closure by mobilization of the skin and subcutaneous tissues. This can be done in large defects of the arm and forearm by extensive undermining of the skin and splitting of the superficial fascia. Skin may be closed under tension provided the sutures are buried under the dermal layer. Cuticular sutures when used to close a wound under tension cut the skin and cause local necrosis and infection. Skin when closed under tension will relax readily and become mobile. The buried sutures may be either interrupted, inverted subcuticular, or continuous subcuticular with the stretch perpendicular to Langer's lines.

Pedicle grafts, flap and tube types, provide both skin and subcutaneous tissues for surface defects. They are also used to provide a vascular cover over tendons, bones, and joints. Pedicle grafts should be attached to surrounding tissue of normal vascularity. Rarely, a pedicle graft may be used primarily for

its subcutaneous tissue. The most suitable site for pedicle grafts providing both thick and thin skin, with or without hair, may be obtained from the lower thorax and abdomen. Direct abdominal flaps offer a quick method of replacing lost tissue. Either the donor area or the base of the flap may be left to granulate in until the time of division. Two flaps, delayed or direct, may be applied simultaneously to two areas. The vertically cut flaps give the best results because the superficial abdominal blood vessels have a vertical pattern. A double pedicle tube graft is not suitable for the forearm and hand except when there is limited pronation and supination in the forearm and lack of motion in the elbow. One stage single pedicle tubes are based inferiorly to include the superficial circumflex iliac or epigastric vein. The latter are especially adaptable for repair of defects of the hand and wrist. Under favorable circumstances when replacement is done, nerves may be sutured, areolar tissue wrapped about tendons, and capsulotomy or arthroplasty may be done. The loss of a side of a finger tip can be corrected by shortening the nail and distal phalanx, and rotation of a flap. When a finger must be amputated its skin may be made available for palmar or dorsal defects by longitudinal splitting of the skin. Z-plasties are recommended for the band type of contracture, the repair of finger webs, longitudinal scars of the fingers or palm, and contracted graft margins. Thick split grafts and full thickness grafts give less contracture than thin split grafts or small deep grafts. Thin full-thickness grafts are available from the lower abdomen, the medial surface of the arm, and the anterior medial thigh.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Kreyberg, L.: Tissue Damage Due to Cold. *Lancet*, Lond., 1946, 1: 338.

This article represents an attempt to summarize and discuss some of the effects of exposure to low temperature, with special reference to the development of necrosis in frostbite and trench foot. The initial reactions to cold are a purely physiological adjustment, and it is not until exposure to cold has lasted for a considerable time that the reactions of the tissues become pathological. Three types of pathological reactions are described: (1) those after a short exposure to moderate cold; (2) those following freezing to ice and return to normal temperature; and (3) those after prolonged exposure to moderate cold not involving freezing to ice (trench foot).

With short exposure to moderate cold, nothing beyond the initial physiological reaction is seen during the exposure. No reaction beyond moderate pain during the exposure indicates tissue damage. Exposure for several hours to very cold air, or for minutes or hours to cold water, may produce the following reaction after the return of the exposed

part to normal surroundings: the exposed part is flushed red with slight pulsation and, for a brief period, raised temperature; the skin is thicker and slightly edematous, and sometimes there is itching, burning, or moderate pain. The clinical picture corresponds exactly with that of moderate sunburn or scald. This is what clinicians call first-degree frostbite. Slight pigmentation may be the end-result. If the exposure has been longer or to a lower temperature, there may be blister formation and a generally more severe reaction. This is clinically known as second-degree frostbite, and, likewise, is very similar to sun and heat reactions. It must be emphasized that light and heat may add to the effect of exposure to cold.

With freezing of the tissues to ice, the ice crystals form on the surface and in the skin. On return to normal environmental temperature, thawing sets in; the whiteness of the frozen skin disappears and is closely followed by a rich red color. In a few minutes a well marked edema can be observed, if the thawing takes place in a heated room. Edema develops much more slowly if thawing is done gently out of doors or in a cold room. The prominent features of the tissues after thawing are hyperemia and edema, which may be severe and accompanied by wheals and blisters, raised temperature, and necrosis. There is a pronounced increase in permeability of the walls of the minute vessels. The series of events that characterizes the intravascular reaction is: cohesion of the blood cells, in the period of development of stasis; intravascular blood cell necrosis, in the next phase; and intravascular hyaline mass formation, as the end result of degeneration of the blood cells. This reaction is quite different from the secondary true thrombosis that may develop at a later stage in or around the tissues undergoing necrosis. The questions arise as to how much of the necrosis is caused by direct action of the cold, and how much is caused secondarily as a result of the vascular stasis. The author cites evidence indicating that freezing of tissues to ice is not necessarily a deadly process like heat coagulation. It has been shown experimentally that the necrosis follows a vascular deficiency caused by a blocking of the blood vessels by red cells.

During prolonged cooling two forms of damage proceed *pari passu*: (1) that due to cooling, and (2) that due to lack of oxygen. One of the first symptoms of prolonged cooling is an increased transudation, with the formation of edema. The edema is augmented when the subject is standing or immobilized (increased hydrostatic pressure), when the limb is constricted (venous congestion), or when the physical condition is poor (hunger, reduced protein and reduced colloid pressure, cardiac or vascular disease). A vicious circle is soon established, with increasing local tissue damage and increased permeability of the minute vessels. The cold prevents a too rapid development, partly by slowing down all activities and partly by the prolonged contraction of the arteries and arterioles. Accordingly, the foot presented at admission is

whitish, bluish, and edematous, with little or no pulsation in the larger arteries. The local edema and the spasm of the arteries are dominant clinical features. The minute vessels may again show mainly dilatation (blue) partly obscured by the severe edema. When the patient is brought under treatment in a room with a higher temperature, the first clinical reaction is re-establishment of the arterial blood flow. The spasm goes, the heat returns, and the skin becomes more or less deep red. The reaction is probably twofold: a reactive hyperemia in its specific sense, and an inflammatory hyperemia caused by tissue damage. Unless the case is of long standing, the tissues in the foot are not dead when the patient is brought under treatment. In trench foot it is still more evident than after freezing to ice that the necrosis of tissues takes considerable time and is not inevitable, and that incorrect treatment may encourage necrosis.

The practical application of these views for the treatment of injuries due to cold is to place frostbite, freezing, trench foot, and allied conditions on the same basis. The return to normal temperature and normal circulation involves the danger of the development of stasis. Medical assistance is of most importance when the tissue is in the stage of pre-stasis. The principles of such treatment have been established empirically:

1. Avoid rapid heating and avoid rubbing.
2. Place the limb in an elevated position and observe the vascular reaction. If the vascular response is rapid and fulminating, with raised temperature of the skin, the limb should be moderately cooled but not returned to an injurious low temperature with ice packs or similar treatment.
3. Keep the skin aired and dry to avoid maceration of the epidermis. JOHN L. LINQVIST, M.D.

Bourdillon, R. B., and Colebrook, L.: Air Hygiene in Dressing Rooms for Burns or Major Wounds. *Lancet*, Lond., 1946, 1: 561, 597.

The bacterial content of the air in the dressing room of a burns unit has been studied with especial reference to the danger of transmitting airborne infection from one patient to the next.

To reduce this danger a forced ventilation plant was installed; this gave highly filtered air at about 10 changes per hour, which later was raised to 20 changes per hour.

A very low incidence of added infections among the burned patients was maintained during 6 months of this study, and analysis suggests that infection by streptococci was not transmitted in any instance in the course of dressing. It is not claimed that this was entirely due to the special provision made for dressing patients in clean air, but it is considered probable that this played an important part.

This result, coupled with extensive studies on the rate of disappearance of air borne organisms from the room, leads the authors to conclude that a supply of fairly clean air equal to 10 changes per hour is adequate for reasonable safety, provided that an inter-

fibrosis which will result. As in the case of capillary nevi, these defects can be closed either by primary suture or by the application of skin grafts, or adjacent skin flaps.

Pigmented nevi are brownish colored lesions varying in shade from café au lait to deeper brown colors. The darker shades of nevi are more likely to take on malignant changes, whereas the large brownish growths, contrary to popular belief, seem to become malignant very rarely. The etiology has not been solved.

For the sake of safety, expediency, and the best cosmetic results, pigmented nevi should be excised, the deep brown colored nevi being excised widely and the adjacent skin edges closed. The larger tumors may be removed by excision and closure either in single or multiple stages, or by the use of a properly selected skin graft.

The author presents 17 cases which illustrate the various points mentioned in his article.

LOUIS T. BYARS, M.D.

Shaw, D. T., and Payne, R. L., Jr.: Repair of Surface Defects of the Upper Extremity. *Ann. Surg.*, 1946, 123: 705.

The selection of the proper type of replacement for surface defects of the upper extremity is dependent upon the amount and degree of tissue loss. Hence a procedure may be as simple as a scar excision or as extensive as a pedicle graft. Scar excision and the removal of foreign bodies, nonvital bone, and irreparably damaged tendon should be done at the time of replacement. Elevation of the extremity and mild pressure dressings are recommended for the prevention of edema and fibrosis. The hand and arm are splinted in the position of function. If damaged and denervated muscles are involved, a neutral position is maintained to prevent contracture. An open wound should be eliminated whenever possible even if it requires a thin split graft as a temporary dressing. Graft margins should be placed in conformity with Langer's lines.

The ideal method in the repair of surface defects is excision of scar tissue and closure by mobilization of the skin and subcutaneous tissues. This can be done in large defects of the arm and forearm by extensive undermining of the skin and splitting of the superficial fascia. Skin may be closed under tension provided the sutures are buried under the dermal layer. Cuticular sutures when used to close a wound under tension cut the skin and cause local necrosis and infection. Skin when closed under tension will relax readily and become mobile. The buried sutures may be either interrupted, inverted subcuticular, or continuous subcuticular with the stretch perpendicular to Langer's lines.

Pedicle grafts, flap and tube types, provide both skin and subcutaneous tissues for surface defects. They are also used to provide a vascular cover over tendons, bones, and joints. Pedicle grafts should be attached to surrounding tissue of normal vascularity. Rarely, a pedicle graft may be used primarily for

its subcutaneous tissue. The most suitable site for pedicle grafts providing both thick and thin skin, with or without hair, may be obtained from the lower thorax and abdomen. It has been shown experimentally that the necrosis follows a vascular deficiency caused by a blocking of the blood vessels by red cells.

During prolonged cooling two forms of damage proceed *pari passu*: (1) that due to cooling, and (2) that due to lack of oxygen. One of the first symptoms of prolonged cooling is an increased transudation, with the formation of edema. The edema is augmented when the subject is standing or immobilized (increased hydrostatic pressure), when the limb is constricted (venous congestion), or when the physical condition is poor (hunger, reduced protein and reduced colloid pressure, cardiac or vascular disease). A vicious circle is soon established, with increasing local tissue damage and increased permeability of the minute vessels. The cold prevents a too rapid development, partly by slowing down all activities and partly by the prolonged contraction of the arteries and arterioles. Accordingly, the foot presented at admission is

whitish, bluish, and edematous, with little or no pulsation in the larger arteries. The local edema and the spasm of the arteries are dominant clinical features. The minute vessels may again show mainly dilatation (blue) partly obscured by the severe edema. When the patient is brought under treatment in a room with a higher temperature, the first clinical reaction is re-establishment of the arterial blood flow. The spasm goes, the beat returns, and the skin becomes more or less deep red. The reaction is probably twofold: a reactive hyperemia in its specific sense, and an inflammatory hyperemia caused by tissue damage. Unless the case is of long standing, the tissues in the foot are not dead when the patient is brought under treatment. In trench foot it is still more evident than after freezing to ice that the necrosis of tissues takes considerable time and is not inevitable, and that incorrect treatment may encourage necrosis.

The practical application of these views for the treatment of injuries due to cold is to place frostbite, freezing, trench foot, and allied conditions on the same basis. The return to normal temperature and normal circulation involves the danger of the development of stasis. Medical assistance is of most importance when the tissue is in the stage of pre-stasis. The principles of such treatment have been established empirically:

1. Avoid rapid heating and avoid rubbing.
2. Place the limb in an elevated position and observe the vascular reaction. If the vascular response is rapid and luminating, with raised temperature of the skin, the limb should be moderately cooled but not returned to an injurious low temperature with ice packs or similar treatment.
3. Keep the skin aired and dry to avoid maceration of the epidermis. JONAS L. LINQVIST, M.D.

Bourdillon, R. B., and Cotchrook, L.: Air Hygiene in Dressing Rooms for Burns or Major Wounds. *Lancet*, Lond., 1946, 1: 561, 597.

The bacterial content of the air in the dressing room of a burns unit has been studied with special reference to the danger of transmitting airborne infection from one patient to the next.

To reduce this danger a forced ventilation plant was installed; this gave highly filtered air at about 10 changes per hour, which later was raised to 20 changes per hour.

A very low incidence of added infections among the burned patients was maintained during 6 months of this study, and analysis suggests that infection by streptococci was not transmitted in any instance in the course of dressing. It is not claimed that this was entirely due to the special provision made for dressing patients in clean air, but it is considered probable that this played an important part.

This result, coupled with extensive studies on the rate of disappearance of air borne organisms from the room, leads the authors to conclude that a supply of fairly clean air equal to 10 changes per hour is adequate for reasonable safety, provided that an inter-

val of at least 5 minutes is enforced between the exit of one patient and the entry of the next, and that unsoiled blankets are not exposed in the dressing room. However, an air supply of from 20 to 30 changes per hour is considered preferable, when practicable.

Standards of air hygiene are proposed as being practicable and desirable for theaters and dressing rooms. It is suggested that hospitals should satisfy themselves about the purity of the air in their operating theaters and dressing stations just as they do of their water and milk supplies.

A new technique of sampling air for bacteria is described; this permits accurate determination of the moments at which clouds of bacteria are liberated. It has shown that large numbers of air borne bacteria are often liberated when dry handages and wool are removed from a patient. These clouds sometimes contain many pathogens. Large clouds may also be liberated by the movement of pajamas or other bed clothes that have been used.

Data are given which confirm the view that unsoiled blankets should not be allowed in any surgical dressing room or theater. JOSEPH GASTER, M.D.

Rountree, P. M., and Armytage, J. E.: Hospital Blankets as a Source of Infection. *Med. J. Australia*, 1946, 1: 503.

The authors' study of the flora of hospital wards was prompted by the findings in other countries, the high incidence of streptococcal infections in Australia, and the occasional occurrence of hemolytic streptococcal infections in surgical wounds.

In a preliminary survey during the winter of 1944, hemolytic streptococci were found in 83 of 122 dust samples cultured from several surgical and ear, nose, and throat wards. The majority of the streptococci were in the Lancefield's A group. Hemolytic streptococci were grown from 35 of 72 throat cultures taken from patients and personnel. A considerable number of persons examined carried group A streptococci without symptoms. A composite dust sample of ward sweepings yielded 250,000 hemolytic streptococci per gram and large numbers of coagulase positive staphylococci.

The present survey carried out during the winter of 1945 investigated the bacterial flora of bed clothes and correlated these findings with the presence or absence of hemolytic streptococci in the wounds or upper respiratory passages of the patients. It also included the examination of dust and air samples from the surgical ward.

The apparatus used to sample the air and blankets was a flow meter similar to that used by Lemon. The apparatus is fully described and its use explained.

In the ear, nose, and throat ward, 3 of 8 throat swabs yielded hemolytic streptococci, and these organisms were found in 2 nasal swabs. Seven of the 37 throat, but none of the nasal swabs taken from the surgical ward were positive for hemolytic streptococci.

Ten of the 24 wounds examined were considered to be infected at or after the operation. The organisms in 10 cases were the staphylococcus aureus, and in 2 the hemolytic streptococci.

Of the 47 blankets examined, 31 yielded hemolytic streptococci. Cultures of 19 of 24 blankets from the male surgical ward and only 3 of 13 from the female ward revealed hemolytic streptococci. The organisms sucked from the blankets varied from 14,400 to 7,344,000 per cubic foot of air. The lowest counts were obtained in new unwashed blankets.

Nine of 16 samples of floor dust and fluff from the surgical ward yielded hemolytic streptococci with a high incidence of group A strains. Forty-four colonies of streptococci were isolated from the male side of the ward as compared to only 1 from the female side. The dust from the floor of the surgical dressing room yielded profuse growths of hemolytic streptococci.

Air samples taken before, during, and after bed making showed a rise in bacterial content of the air during bed making. However, no hemolytic streptococci were isolated, probably because samples were collected from areas near beds from which no streptococci were recovered either from the blankets or the occupants. In the previous winter hemolytic streptococci were grown on 9 of 10 plates exposed during bed making.

This survey showed the presence of considerable numbers of hemolytic streptococci in the dust samples of surgical and ear, nose, and throat wards. It also established the fact that dangerous wound pathogens—namely hemolytic streptococci—were present in the blankets. In 5 cases with wounds contaminated by hemolytic streptococci, the numbers of streptococci isolated from the blankets were considerably higher than those from other blankets.

With 1 exception, the blankets of the 10 patients with hemolytic streptococci on their throat cultures, yielded hemolytic streptococci.

There was a high incidence of wound infection—many cases with staphylococci. The authors suggest further investigation with phage typing of the staphylococci.

The problem of air-borne infection must be dealt with by using aseptic techniques in dressing surgical wounds and oiling floors to lay the dust.

Blanket laundering is adequate for sterilization but the frequency of washing is insufficient.

The oiling of blankets reduces the number of infected dust particles in the air, but there is no evidence that it prevents possible direct infection from blanket to wound. Further investigations of the measures necessary to overcome this problem are required.

Rountree, P. M.: The Treatment of Hospital Blankets with Oil Emulsions and the Bactericidal Action of "Fizanol C" (Cetyl Pyridinium Bromide). *Med. J. Australia*, 1946, 1: 539.

The author reports the results of an experimental study of the bactericidal effect of a chemical agent,

cetyl pyridinium bromide, "fixanol C", on a group of pathogenic organisms found on hospital blankets.

Previous studies by the author in 1946 showed that hospital blankets carried a heavy load of micro-organisms, and that blankets should be regarded as dangerous sources of bacteria causing wound infections.

The bacteriostatic and bactericidal action of fixanol in oil-water emulsions sprayed onto fluff, and the bactericidal power of fixanol in oil-water emulsions used to impregnate blankets, were determined.

Ten species of gram-positive organisms, including a number of different strains of hemolytic streptococci, pneumococci, and staphylococci, were examined. With the exception of one strain of *Bacillus subtilis*, one strain of *Clostridium histolyticum*, and one strain of *Corynebacterium diphtheriae*, the concentration of fixanol inhibiting growth was either 1 in 200,000 or 1 in 400,000, 28 strains in all being tested. The culture of *Clostridium histolyticum* used was inhibited by a 1 in 100,000 dilution and the strain of *Bacillus subtilis* by a 1 in 10,000 dilution. The strain of *Corynebacterium diphtheriae* was inhibited by a dilution of 1 in 32,000. The results indicate that fixanol possesses a high degree of bacteriostatic activity against gram-positive organisms.

A low order of activity was shown against the 12 species of gram-negative organisms tested—dilutions ranging from 1 in 1,000 to 1 in 10,000 being the highest concentration which inhibited growth. There were two exceptions to this—*Shigella paradysenteriae* Flexner, two strains of which were inhibited by a concentration of 1 to 100,000, and *Neisseria gonorrhoeae*, three freshly isolated strains of which were inhibited by a concentration of 1 to 100,000.

Fixanol in vitro in a concentration of 1 in 5,000 showed bactericidal activity against various strains of hemolytic streptococci, *Staphylococcus aureus*, *Proteus vulgaris*, and *Mycobacterium phlei*.

Fixanol C, the active principle of which is cetyl pyridinium bromide, is an active bactericide against a large number of gram-positive and gram-negative organisms found on hospital blankets. Fixanol C, when incorporated in an oil-water emulsion and sprayed onto hemolytic streptococci dried on sterile fluff, rapidly kills these bacteria. Fixanol C, when impregnated into blankets in a concentration of 1 to 800, imparts an efficient bactericidal action to blankets so treated. Blankets treated with fixanol C and oil retain their bactericidal power for periods of at least 3 months.

It is realized that cross infection in hospital wards depends on many factors, and it is not suggested that an oil, plus antiseptic, treatment of blankets will eliminate it. However, it is considered that such treatment should substantially reduce the load of bacteria added to the air during bed-making, and should also reduce the chances that wound infection would be transmitted from infected blankets to patients.

The use of fixanol to impregnate oiled blankets at a concentration of 1 to 800 should prove to be of

value in the control of cross infection in hospital wards, in the nursing of both surgical patients and patients with infectious diseases. Blankets treated in this manner have only a slightly oily texture and no perceptible odor.

JOHN H. MOHARDT, M.D.

Stammers, F.A.R., MacLennan, J. D., Macfarlane, M., Hartley, Sir P., and Evans, D. G.: Discussion on the Toxemia of Gas Gangrene. *Proc. R. Soc. M., Lond.*, 1946, 39: 291.

Gas gangrene is discussed in detail, and the experience of British surgeons with it is reported in this article. Although almost nothing was known of the disease before 1914, much accurate knowledge was accumulated during and after World War I.

Gas gangrene is an infection of devitalized muscle by gas-forming organisms, though fascia, blood clot, and brain are susceptible. The mere presence of clostridia in a wound is not sufficient. Defective blood supply, damaged muscle, and clostridia are the essential factors, and major muscle wounds such as those of the buttocks, thigh, calf, and scapuloaxillary regions are especially liable to gas infections.

Missiles, such as jagged pieces of shell, mine and mortar, cause more disruption of tissue than do bullets, and indriven pieces of dirty clothing or equipment are especially damaging. Anything affecting the blood supply, directly or indirectly, encourages the disease. Injury to blood vessels, tourniquets, tight bandaging, incorrectly applied splints, and ambulance journeys over rough roads all embarrass the blood supply, but the general lowering of the blood pressure resulting from hemorrhage, shock, dehydration, exposure to wet and cold, further contributes to the liability of gas gangrene.

Of special significance is the observation from all fronts that something is absorbed from damaged muscle that leads to a prolonged lowering of blood pressure, which later will encourage gas gangrene if clostridia be present. There is a close resemblance between the case of gas gangrene toxemia and the case of absorption of the products of lacerated muscle. A report by MacFarlane and MacLennan (January, 1945) suggests that part of the syndrome of gas gangrene toxemia was due to the absorption of the products of breakdown of muscle resulting from clostridial infection of it.

Time is an important factor. It has been shown repeatedly that infection in wounds remains relatively superficial for the first 8 to 12 hours, but that after this time the deeper tissues become involved. Delay in applying surgical treatment until after this optimum interval encourages sepsis and the risk of gas gangrene.

From the surgical point of view, cases may be divided into the established case (as, for instance, in men who could not be rescued for many hours), an unexpected finding at operation, or a complication developing after the first operation—a very rare event. Patients whose collection had been delayed were admitted prostrated, with cold, blue, clammy extremities, running pulse, the wounded part being

painful, swollen, livid, or mottled, and becoming plum-colored from hemolysis. Gas might or might not be present; it could often be detected with varying pressure of the stethoscope, earlier or more readily than with the fingers. If muscle was exposed it was dry and dull, and discharges were no more than a foul smelling thin fluid. Sometimes jaundice developed. In the case discovered unexpectedly at operation, one or more affected muscles of a group, or part only of one muscle belly, with clear demarcation between normal and abnormal, are discovered during exploration of the wound. The affected muscles may be salmon pink or red, and only in extreme cases black and diffuent, and in any case they do not contract or bleed when cut. The surrounding tissues may be normal or distended with yellow edema, and fine gas bubbles may be seen in both muscle and intermuscular septa. In the case developing after operation, the onset is sudden. There is local pain, malaise, rising temperature and pulse, and sometimes vomiting, but the outstanding and most characteristic feature is the toxemia. From a relatively normal individual, the patient will within a few hours become anxious, euphoric, or wildly excited, and the pulse rapidly deteriorates. Such a patient is near the end, and he may reach for a drink and die in the act. In the earlier days of the war, much importance was attached to the development of pain, but during the last 12 months in Italy, many surgeons remarked on the absence of pain, probably the consequence of better and earlier surgery, aided by penicillin therapy in the control of secondary infection.

Less than 50 per cent of patients develop gas. In the past, unnecessary amputations have been performed because of the presence of emphysema locally in the absence of the clinical picture. Muscle fibers, cut suddenly by a sharp fragment of metal, spring apart and, like the piston of a syringe, may aspirate air through the skin wound into the gap. The air disseminates rapidly and may be diagnosed as gas. The absence of evidence of toxemia should obviate this error.

The essentials of treatment are early, adequate surgery, blood, blood plasma, intravenous fluids, antitoxin, penicillin, and adequate immobilization and protection of the wound against secondary infection.

The treatment of gas gangrene is primarily preventive and the disease can be almost eliminated by proper medical organization. Every surgical case should receive treatment within 2 to 6 hours of wounding, and all the remainder within 12 hours. At the earliest possible moment all major wounds were given sufficient antitoxin to contain 8,000 units of anticlostridial welchii. All major muscle wounds—calf, thigh, buttock, and scapuloaxillary region—were regarded as top priority cases, but even small muscle wounds were treated by careful excision too. Wounds were dressed and carefully splinted at the earliest moment practicable. Because of the effect on blood pressure of massive injury to muscles of

over 3 hours standing, too much time was not spent on resuscitation; surgical intervention was considered the essential procedure.

Adequate incisions are needed for careful exploration of the wound. All foreign material must be sought for and removed, the wound carefully irrigated with saline solution, and all affected muscle excised. The complete muscle belly is excised from origin to insertion when practicable, though in large muscles like the adductor magnus it may be necessary to remove only a part of it. All discolored muscle, and muscle that does not bleed or contract when cut, should be removed. Deep fasciae are incised transversely and longitudinally for decompression and drainage. The wound is frosted heavily with penicillin powder, and the skin is left open but dressed with dry gauze. Enormous amounts of muscle may have to be sacrificed (as, for instance, the entire gluteal muscles), and a limb may be so disorganized as to require immediate amputation, but the amputation rate has declined in proportion to the application of better prophylactic surgery. These patients require blood plasma and fluids. This should include one bottle of plasma daily to replenish protein, and blood should be given according to hemoglobin determinations. The volume to be administered was determined by Van Slyke's copper sulfate test. At the end of operation 100,000 units of antitoxin were injected and the patients were placed on a schedule of 15,000 units of penicillin every 3 hours for about 3 to 7 days. The discussant is not convinced that penicillin affected the clostridial infection but is sure that penicillin controlled secondary pyogenic infection.

In discussing the pathogenesis, MacLennan and MacFarlane emphasize the importance of clostridia welchii in this disease and favor the view that the alpha-toxin is the component of prime importance and that the others of the many enzymes elaborated by clostridia welchii play a subsidiary role in the intense necrosis and tissue reactions seen in gas gangrene. Several causes of the toxemia of gas gangrene are postulated: (1) action of the specific bacterial toxin on vital organs; (2) production of nonspecific toxic substances by the infecting organism; and (3) toxemia due to ischemic muscles. A component of importance in the toxemia is the nonhemolytic toxic factor, not neutralized by antitoxin and derived from disintegrating muscles, as may be observed in severe muscle trauma, crush syndrome, and related states.

The decline in mortality, from over 50 per cent in Italy in 1940, to 30 per cent in 1944, is attributed to intensive use of antitoxin and improved surgery. With the best treatment possible, including penicillin, the death rate remained about 25 per cent. The fact that with the best treatment possible the death rate remained about 25 per cent, indicates the existence of another cause of toxemia in addition to the bacterial toxin, and it is suggested that this may be the added toxemia of disintegrating muscle.

JOHN H. MONARDT, M.D.

Lemierre, A., Reilly, J., Morin, M., and Rathery, M.: The Effect of Penicillin on Septicemia Caused by Anaerobic Microbes (Action de la pénicilline dans quelques septicémies à microbes anaérobies). *Presse méd.*, 1946, 54: 49.

The authors employed penicillin in 9 patients with septicemia caused by the bacillus perfringens or the bacillus funduliformis.

Although, as a rule, an infection caused by the first mentioned micro-organism is nearly always fatal, in 2 women the administration of penicillin suppressed the septicemia nearly immediately and the bacteriologic examination of the blood, urine, and lochia gave negative results. However, of 3 patients suffering from a septicemia caused by the bacillus perfringens 2 died. The fatal outcome was probably due to the colon bacilli which are resistant to penicillin.

In patients with tonsillitis, especially the phlegmonous type, the early administration of penicillin prevents secondary localization of the infection, e.g., pulmonary infarcts or arthritis.

The authors found that certain species of bacillus funduliformis respond well to the treatment with penicillin, while others are apparently resistant to the drug.

On the whole, the beneficial effect of penicillin is more striking in the treatment of septicemia caused

by the bacillus funduliformis than in postabortum cases of septicemia for which the bacillus perfringens is responsible.

JOSEPH K. NARAT, M.D.

ANESTHESIA

Corlette, C. E.: Spinal Anesthesia and Chloroform; A Comparison of Mortality. *Med. J. Australia*, 1946, 1: 545.

The author has made a survey of the literature to find the recorded over-all mortality of spinal anesthesia and to compare it with that of chloroform anesthesia. The results offer food for thought and matter for much consideration.

If two collections of cases are added, there is a total of 35,612 administrations of chloroform with 32 deaths. This is a mortality rate of 8.9 in 10,000.

Three series which include a total of 20,012 cases of spinal anesthesia with 54 deaths are reviewed. This is a mortality rate of 26.9 in 10,000, three times the death rate calculated from the chloroform anesthetics.

If the statistics are soundly based, the chloroform anesthesia of 50 years ago was at least twice as safe as the spinal anesthesia, and, on the average, it was probably three times as safe.

MARY FRANCES POE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Neuhauser, E. B. D.: Roentgen Changes Associated with Pancreatic Insufficiency in Early Life. *Radiology*, 1946, 46: 319.

The author calls attention to the increasing recognition of pancreatic fibrosis as a cause of death in infants and young children, and cites the records of the Infant's and Children's Hospital of Boston, Massachusetts, in the year 1942 as showing that 12 per cent of the autopsied cases exhibit a significant degree of pancreatic fibrosis. He bases this article on more than 50 cases of this disease studied there.

The clinical and pathological findings of the disease are briefly reviewed with stress on Farber's work. Pancreatic fibrosis in infants may be due to some local process such as atresia or stenosis of the pancreatic ducts, or duct obstruction due to an annular pancreas, but in the majority of cases it is regarded as but one manifestation of a widespread disturbance in which there is failure of formation or of liberation of pancreatic enzymes and an alteration in the physical character of secretions from many organs, including glands of the trachea, bronchi, and intestinal tract.

If the reduction of pancreatic enzyme activity occurs before birth a physical alteration in meconium causes it to have a sticky mucilaginous quality which may lead to obstruction of the ileum and colon. Infants so affected are usually admitted to the hospital in the first week of life with signs and symptoms of intestinal obstruction, and frequently the roentgen findings admit of no more specific diagnosis than small bowel obstruction of undetermined origin, with perhaps a rough localization of the region involved. However, in some of the infants abdominal films have shown minute bubbles of gas scattered throughout the distal small bowel with some reduction of bowel caliber in this region as compared with the gas distended more proximal bowel. The author believes this appearance is due to the fact that gas bubbles are forced into an obstructing mass of abnormally tenacious meconium and therefore diagnostic of meconium ileus. He has not seen this pattern in any other condition of the newborn. In the last 10 cases of meconium ileus at this hospital the correct diagnosis was made roentgenologically in 4.

Disturbance in the motor pattern of the bowel after a barium meal was not recognizable in cases of pancreatic fibrosis in young infants, as the pattern is known to vary widely in apparently normal individuals at this early age. In some of the older infants showing the nutritional failure that is so prominent a feature of the disease, there was evidence of bowel hypertonicity and segmental dilatation with clumping and discontinuity of the barium column, but only rarely did the rugal folds

of the duodenum and jejunum appear coarsened in the manner encountered by Golden on the examination of older children and adults with nutritional deficiency states.

If pancreatic fibrosis is part of a generalized disease process, there is almost always evidence of chronic pulmonary disease, which in its early stage appears to be due to bronchial obstruction produced by the thick, glairy tenacious character of the tracheobronchial secretions. This stage is manifested roentgenologically by flattening and depression of the diaphragm, increased pulmonary radiolucency even in expiration, and widening of the intercostal spaces which is indicative of obstructive emphysema. The emphysema tends to be patchy, interspersed with lobular areas of atelectasis.

In the later stages of the disease pulmonary infection ensues and the roentgen appearance of the lungs changes sharply. The hilar shadows become markedly accentuated, and lines and patches of increased density cast by peribronchial pneumonic infiltrate radiate from them. Bronchiectasis develops. The end stage shows evidence of long standing pulmonary disease characterized by emphysema, atelectasis, fibrosis, and widespread infection involving all lobes but not, in the author's experience, the pleura. The author believes that this appearance, although not pathognomonic, is sufficient to suggest a diagnosis of pancreatic fibrosis in these young children, subject to confirmation by examination of the duodenal content for a reduction in the pancreatic enzymes. LILIAN DONALDSON, M.D.

Holt, J. F.: The Roentgen Diagnosis of Pancreatic Cyst. *Radiology*, 1946, 46: 319.

The author briefly summarizes the roentgen findings in cyst of the pancreas as revealed by a brief review of the literature and the observation of 13 patients who had had surgical treatment for pancreatic cyst at University Hospital, Ann Arbor, Michigan. The roentgen appearance, of course, varies according to the size of the cyst and the region of the pancreas from which it arises. Occasionally the cyst is visible as a soft tissue mass in films of the abdomen, but more frequently it reveals its presence indirectly by the pressure defects it produces in the barium filled stomach, proximal small bowel, and colon.

Cysts arising in the head of the pancreas may produce widening of the duodenal loop with little or no deformity of the stomach, whereas cysts of the body of the pancreas usually displace the stomach anterosuperiorly, with variable associated distortion of the proximal small bowel. Occasionally, cysts of the body may present superiorly and medially to the stomach which results in wide smooth indentation of the lesser curvature. The more common cyst of the tail of the pancreas, on the other hand, fre-

quently causes smooth rounded indentation of the upper or midportion of the greater curvature of the body of the stomach and lateral views show the stomach displaced anteriorly. In addition, the duodenojejunal flexure is displaced downward and the splenic flexure of the colon may be depressed or indented along its medial aspect. Of the 13 patients treated at University Hospital, 7 had a cyst arising in the tail of the pancreas, and films showed this deformity of the greater curvature of the stomach.

In the differential diagnosis, enlarged spleen, splenic cyst, mesenteric or omental cyst, and retroperitoneal neoplasm might conceivably produce such a deformity of the greater curvature of the stomach, but search of the files at University Hospital for such extra-alimentary masses revealed only 2 instances—a congenital cyst of wolffian body origin, and a neoplasm of the lower pole of the left kidney (identified by pyelography), which caused both greater curvature deformity and anterior displacement of the stomach.

The author therefore believes that these findings encountered in conjunction with a rounded ballotable, freely movable mass in the left upper quadrant of the abdomen enable the roentgenologist to make a diagnosis of pancreatic cyst with reasonable assurance and surmise in what portion of the pancreas it is located. The author does not discuss the findings in carcinoma of the pancreas.

LILIAN DONALDSON, M.D.

Dell, J. M., Jr., and Klinefelter, H. F., Jr.: Roentgen Studies of the Spleen. *Am. J. M. Sc.*, 1946, 111: 437.

During the last 18 months the authors made routine roentgen studies of the spleen in 300 patients in an Army General Hospital. In 50 per cent the spleen was enlarged, mostly due to malaria, and the other 50 per cent, which acted as a control group, consisted of neuropsychiatric, general medical and surgical patients.

The technique was very simple. Without any preliminary preparation, posteroanterior roentgenograms were made on an empty stomach. The central ray was directed through a point halfway between the midline and the left lateral chest wall, three finger breadths below the xiphoid cartilage. The exposure factors were 100 milliamperes, 0.5 second, 36 inch skin target distance, Potter-Bucky diaphragm, and a kilovoltage varying with the thickness of the patient, but on an average from 6 to 8 kilovolts less than in the standard stomach technique.

The size of the spleen was estimated on the basis of its own measurable dimensions and a comparison with the size of the left kidney. Anatomically, the normal spleen of an adult is about 12 centimeters in length, 7 centimeters in breadth, and 3 to 4 centimeters in thickness, and the normal kidney 11½ centimeters in length, 5 to 7½ centimeters in breadth, and 2½ to 3 centimeters in thickness. Because of the fact that in the above described projection the magnification of the kidney is greater than

TABLE I.—A SUMMARY OF CRITERIA USED

Interpretation	Width	Density
Normal	Less than 5 cm 5 to 5.5 cm.	Normal or increased Normal
Questionably enlarged	5 to 5.5 cm 5.5 to 6 cm	Increased Normal
Enlarged	5.5 to 6 cm More than 6 cm.	Increased Normal or increased

Any spleen less than 85 per cent of the size of the kidney is not enlarged; any spleen more than 85 per cent of the size of the kidney is enlarged.

that of the spleen, the authors arbitrarily considered any spleen which is more than 85 per cent of the size of the kidney as enlarged.

Some difficulty was encountered in measuring the dimensions of the spleen proper, since, due to the oblique position, the roentgen shadow represents a combination of the anatomic breadth and thickness. The authors measured the width at the broadest possible point, which usually is just below the hilus, to the outer border of the spleen when this was visible, or to the internal surface of the ribs when the border was not visible. Since the spleen is rarely visualized in its entire length, this dimension could not be measured.

Rotation of the spleen on its long axis alters its width; therefore the authors found it necessary to consider also the density of the spleen. This was done by comparing it with the density of the lower half of the left kidney. The density of the spleen was regarded as increased when found greater than that of the normal kidney.

The criteria established are presented in Table I.

In a further study, the authors found no diurnal variation in the size of the spleen or any change due to the ingestion of food or moderate activity. The subcutaneous injection of adrenalin, however, resulted within 5 to 15 minutes in a definite decrease in the size of the spleen.

The conclusion is reached that the roentgen examination of the spleen is a valuable method. Many palpable spleens are not enlarged and many enlarged spleens are not palpable.

T. LEUCUTH, M.D.

Meschan, J.: A Radiographic Analysis of Spondylolisthesis. *Med. J. Australia*, 1946, 1: 465.

Spondylolisthesis is due to a defect in the isthmus of the articular processes. The defect is the result of trauma early in life or is due to lack of ossification of the isthmus. Trauma, sooner or later, invariably aggravates the condition.

The defect is best seen in the oblique views at an angle of 45 degrees. At an army base, 11.7 per cent of 520 roentgen examinations of the lumbosacral area revealed defects of the pars interarticularis and in two-thirds of this number the defects were bilateral.

The mechanism of spondylolisthesis takes place in an arc fashion, whereby the inferior part of the vertebra moves forward while the superior apophyseal joint acts as a pivot.

Fig. 1. Tracings of roentgenographs of subjects with spondylolisthesis; the lines either intersect above the fifth lumbar vertebra and form an angle exceeding 3 degrees,

as shown in (A) and (B), or remain parallel, but are more than 3 mm. apart as in (C).

The lateral roentgenogram is most accurate for detecting spondylolisthesis. The degree of displacement is measured by plotting lines between the inferior posterior border of the vertebrae above the involved one to the posterior superior edge of the vertebrae below the one in question (usually the first sacral), and another line from the posterior superior to the posterior inferior border of the involved vertebra. The two lines are close together and may cross above or below the involved vertebra; the separation angle is never above 3 degrees, nor is the separation of both lines, when parallel, more than 4 mm. In spondylolisthesis the separation angle is more than 3 degrees (from 12 to 16) and the parallel lines are more than 4 mm.

Stability of the vertebra is determined by means of upright films taken during weight bearing and in flexion and extension.

With this criterion, a defect of the isthmus was found in 55 of 520 patients whose lumbosacral spine was examined. All of the defects were in the lumbar vertebra except 1, which was found in the twelfth dorsal vertebra. Forty-two patients had bilateral defects; of this number, 62 per cent had definite vertebral displacement, and 19 per cent had borderline vertebral displacement, and 19 per cent showed no displacement. Stability tests were done on 26 patients with roentgen evidence of spondylolisthesis, and in 14 cases instability was present. Anterior tipping of the vertebral body was interpreted to be the result of undue strain on the anterior spinous ligaments. There was no correlation between the degree of vertebral displacement and stability. Stability tests should be done in all cases of spondylolisthesis.

RADIUM

Windeyer, B. W., Nuttall, J. R., Splers, F. W., Stewart, F. S., and Others: Symposium—Dosage Control in Interstitial Radium Therapy. *Brit. J. Radiol.*, 1936, 29: 233.

With the advent of radium as a therapeutic agent, several problems were immediately presented:

1. With the use of glass radon seeds, necrosis was found in the immediate area. (It was obvious that a better quality ray was needed.)
2. With the help of physicists, it was found that a more even distribution of radiation could be brought about by placement of needles or tubes around the periphery of the tumor, or, interstitially, approximately 1 cm. apart.
3. More accurate knowledge was found to be needed of tumor types and sites, and their response to radiation, in order to judge better the amount to be given.

In addition, the following problems must be considered and solved:

1. Difficulty of radium accessibility to tumor.
2. Tumors friable, so that needles move in tumor.
3. If inserted into a taut lesion, radium needles' position variable with the release of tension on lesion.
4. Correlation of kind of radium implants with the type of tumor.
5. Radium position dependent on movement of patient.

In order to control these sources of error, x-ray films should be taken in at least two planes with radium in position; also, a better method of radium implantation and a better method of estimating necessary tumor dosages are required.

An alternate method of demonstrating radium implantation in estimating tumor dosage may be used by taking two exposures on one film and shifting the tube for the second exposure.

Physicist and radiation therapist should work together in close harmony in order to achieve greater accuracy in the implantation of radium. All available methods which will be of aid to the physician should be used.

The therapeutic efficacy of radium and x-ray therapy in neoplasms is dependent on a minimal lethal tumor dose over a correct period of time. Planned treatments should call for a minimal, maximum, and general average tumor dose.

The difficulties of radium implantation are discussed. Inasmuch as it is difficult to insert radium needles parallel to each other, especially if the tumor contour is irregular, many devices have been tried; however, none has been entirely satisfactory. The author has developed an interstitial condenser for measuring relatively low dosages. This condenser is small, and in order to avoid steep variations in dosage near the radium, it must not be asymmetrical. The dose rate must be from 30 to 50 r/hour, in 5 to 10 day treatments. The exposure time is 1 minute. The condenser may be sterilized for use in the operating room by enclosure in a dry sheath.

Since condensers cannot be boiled or immersed in antiseptic solutions, a trocar type of cannula has been devised for this purpose. The cannula may be inserted into the tumor and the condenser inserted into it for measuring purposes, which is done in terms of volts. Sensitivity in volts lost per roentgen varies with the type of condenser used.

Several cases are presented in which the dosage has been calibrated by two-plane x-ray films and condenser units. The results convince the author of its value, especially in those instances in which it is impossible to take two-plane films.

The use of nonuniform loading radon needles is advocated in those cases in which the tumor volume creates technical difficulties. By so doing, the uniform dose of a needle may be raised from 60 to 85 per cent, and even to 92 per cent of the active length of the needle. A Geiger-Müller counter can also be used as a dosimeter in the measurement of interstitial radium implantation.

A serviceable lethal tumor dose for epitheliomas is estimated at 6,000 r. delivered in from 7 to 10 days. Tongue, skin, and breast lesions can tolerate 5,500 to 7,000 r.

An effective tumor dose is dependent on the cellular activity of repair and proliferation, and radio

resistance. Maintenance of viable connective tissue is just as important as the deliverance of a tumor dose.

The authors state that with the use of the volume dosage system, as devised by Patterson, one could estimate a tumor dose for any given volume of tumor.

Koller, P. C., and Smlthers, D. W.: Cytological Analysis of the Response of Malignant Tumors to Irradiation as an Approach to a Biological Basis for Dosage in Radiotherapy. *Brit. J. Radiol.* 1946, 19: 89.

The authors tried to determine the optimal tumor dose and the optimal mode of fractionation in the irradiation treatment of neoplasms.

This attempt is based on the assumption that the response of the tumor to irradiation depends upon at least two different reactions: an intracellular and an intercellular one. The former occurs prior to the latter. The treatments have to be phased according to their cycle. Furthermore, the intensity of the irradiation and the amount of irradiation has to be selected so as not to suppress the second reaction too much while the first one is to be produced; and, vice versa, the first one must not be too weak and therefore allow the second reaction to stimulate a tumor-protective process in the tumor bed.

This assumption has now been better supported by the cytological experiments of one of the authors, as well as by irradiation of tumors in animals and patients followed up by a great number of biopsies by the other author.

It was found that the optimal tumor dose varies not only with the type of tumor but also with different tumors of the same histological appearance. The fractionation and termination of the treatments was guided by repeated biopsies, except in the case of deep seated tumors which did not lend themselves to frequent biopsies.

The authors draw the following conclusions:

1. Fractionated treatment is superior to single dose treatment, (a) because a greater number of cells can be affected in a sensitive phase (intracellular reaction), and (b) because the second phase of the irradiation reaction may be controlled (intercellular reaction).

2. Routine fractionation consisting of equal daily doses should be abandoned in favor of individually graduated time dosage distribution guided by cytological control of the tumor while the treatment proceeds.

GERNART S. SCHWARZ, M.D.

Fig. 1. Tracings of roentgenographs of subjects with spondylolisthesis; the lines either intersect above the fifth lumbar vertebra and form an angle exceeding 3 degrees,

as shown in (A) and (B), or remain parallel, but are more than 3 mm. apart as in (C).

The lateral roentgenogram is most accurate for detecting spondylolisthesis. The degree of displacement is measured by plotting lines between the inferior posterior border of the vertebrae above the involved one to the posterior superior edge of the vertebra below the one in question (usually the first sacral), and another line from the posterior superior to the posterior inferior border of the involved vertebra. The two lines are close together and may cross above or below the involved vertebra; the separation angle is never above 3 degrees, nor is the separation of both lines, when parallel, more than 4 mm. In spondylolisthesis the separation angle is more than 3 degrees (from 12 to 16) and the parallel lines are more than 4 mm.

Stability of the vertebra is determined by means of upright films taken during weight bearing and in flexion and extension.

With this criterion, a defect of the isthmus was found in 55 of 520 patients whose lumbosacral spine was examined. All of the defects were in the lumbar vertebra except 1, which was found in the twelfth dorsal vertebra. Forty-two patients had bilateral defects; of this number, 62 per cent had definite vertebral displacement, and 19 per cent had borderline vertebral displacement, and 19 per cent showed no displacement. Stability tests were done on 26 patients with roentgen evidence of spondylolisthesis, and in 14 cases instability was present. Anterior slipping of the vertebral body was interpreted to be the result of undue strain on the anterior spinous ligaments. There was no correlation between the degree of vertebral displacement and stability. Stability tests should be done in all cases of spondylolisthesis.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Corey, E. L.: Medical Aspects of Blast. *U. S. Nav. M. Bull.*, 1946, 46: 623.

The term "blast" has been used to identify the intense sound wave emanating from a detonated explosive. As a result of poor usage of the term, it is now used to describe true air blast, underwater concussion, transmitted impact through hulls, ground shock, and the after vibration of walls and other structures. The author suggests that the term "explosion pressure" would be more precise, thus enabling one to refer to "explosion pressure in air" or "explosion pressure in water" while using the terms "ground shock," impact transmission through solids, and similar terms wherever they may convey the most precise meaning.

Blast may be defined as the compression (and in air, the suction) wave which is set up by the detonation of an explosive. A blast wave in air is composed of a pressure, followed by a suction component, the latter being of much longer duration than the compression phase (approximately 0.0006 and 0.03 seconds, respectively). The positive phase may exert pressures measured in hundreds of pounds per square inch (close to the charge), whereas the negative pressure can never exceed 25 pounds per square inch because it corresponds to a perfect vacuum. The velocity and duration of either phase are such that the body of a man would be completely immersed for an instant in a wave of almost uniformly altered pressure.

A blast wave is, physically, simply a very intense sound wave. Thus, although the velocity with which the blast travels close to a charge varies with the "power" of the explosive (volume of gas produced multiplied by heat generated), it is quickly reduced to the speed of sound, and decreases in pressure as the square of the distance. This is true of blast waves generated in either air or water, and indeed of the rate of transmission of a blast wave through any material, including the human body.

Since a blast wave is essentially an intense sound wave, its velocity varies with temperature. About 1,100 feet per second may be taken as an average figure, in air; in water its velocity approximates 4,800 feet per second, and peak pressures generated are much more severe than in air. As the human body is about 75 per cent water, the blast wave will traverse the tissues at over 4,000 feet per second. As in air, the "shock front" or compression wave is of sufficient thickness to impose uniformly elevated pressures on all parts of the body of swimmers or divers simultaneously.

Blast pressure is profoundly affected by the nature of the terrain. Thus, its intensity is greatly diminished within depressions such as foxholes, trenches

and ditches, and directly behind trees, bunkers, and walls. On the other hand, the blast wave is reflected from vertical surfaces, theoretically increasing the peak pressure by 100 per cent. Actually, the pressure caused by "reflectance" falls slightly short of this figure. Reflectance from the ground, cliffs, and walls of buildings, together with that under water, from the shoreline, hulls of vessels, and from docks and pilings, may produce many almost unpredictable variations in pressure. In water, temperature gradients between the surface and the bottom distort the "shock front" and cause it to curve toward the colder strata. Hence, with a surface temperature above that at the bottom of even shallow water, the shock front is very perceptibly "bent" toward the bottom, rather than travelling in a straight and horizontal direction. When these variables are introduced, the freakish and almost unpredictable results of a blast may be understood.

The single type of lesion uniformly present in air blast is "bruising and rupture of the lungs." Pulmonary damage may be either slight or severe, its extent depending upon the magnitude of the blast pressure. Thus lesions may vary from small punctate areas to massive hemorrhage with hemothorax. The cause of this type of injury is the positive phase of the blast, although similar lesions may be caused by explosive decompression. Yet, experience with explosive decompression in man (aviation medicine) indicates that decompression in air, even at rapid rates, is relatively harmless. Although the pulmonary lesions are those most commonly encountered, there is no doubt that sufficiently elevated pressures may produce rupture of the gastrointestinal tract. That air blast per se is ineffective at any considerable distance from even large charges has been effectively shown in animal experiments and from a study of the casualties resulting from the blast which occurred at the Naval Air Station, Norfolk, Virginia, in September, 1943, when several Torpedoes were accidentally detonated. After a careful study of the 35 casualties from this explosion, it was concluded that (1) "blast injury" is probably not a major factor in producing injuries from large bomb explosions, inasmuch as no recognizable cases of "blast lung" were observed following the Norfolk disaster, and (2) such explosions produce terribly mutilating injuries from missiles as well as burns ranging from first to third degree.

During World War II, underwater blast has been a far greater producer of casualties than has blast in air. This is due to the greater intensity of an underwater concussion for a given weight of charge. The pathology found in these cases has been described by Greaves *et al*, and may be considered typical of this type of injury in all details. In cases of severe injury, the lungs are characterized by diffuse hemorrhage throughout the entire parenchyma, very little

istered systemically to control impending or established invasive infection¹

The ability to check invasive infection by chemotherapy freed the surgeon from inhibitions that long have stayed his hand. The fear of fanning the fires of infection by the surgical manipulation of infected tissues following trauma was banished. A bold revolution in the management of wounds took place. This has led to changes in the basic concept of the surgical approach to wounds and traumatic injuries.

REPARATIVE SURGERY

By the acceptance of the term "reparative surgery" in a War Department Technical Bulletin (TB MED 147, March, 1945), the Surgical Consultants Division of the Office of The Surgeon General gave official recognition to a concept of wound management that originated in the Mediterranean Theater of Operations. The validity of the concept was strengthened by subsequent experience in the field. The cessation of combat in northern Italy found it firmly established among the surgeons of the Theater.

This phase of wound surgery follows the 'debridement' or initial wound surgery established as a basic procedure in World War I and perpetuated in the recent war as the key stone of wound management. Reparative surgery has been described as follows: "A highly significant and far reaching advance in military surgery has taken place in the base hospitals with the development of what may be called reparative surgery. Wounds left unsutured at the initial operation are routinely closed by suture usually at the time of the first dressing. With the use of penicillin as a safeguard against infection, the management of wounds complicated by fracture or joint involvement has been revolutionized. Surgical procedures in special fields of surgery—thoracic,

cranio-cerebral, abdominal—have also been radically altered by the application of similar principles. The significance of this development and its effect on returning an increased number of wounded soldiers to duty and in preventing deformity, disability, and death in the seriously wounded can hardly be overestimated.

"Reparative surgery is not to be confused with the reconstructive surgery of the Zone of the Interior. Reparative surgery is designed to prevent or cut short wound infection either before it is established or at the period of its inception. Once established wound infection is destructive of tissue and at times of life. In many instances it permanently precludes the restoration of function by the most skillful reconstructive efforts.

"If the initial wound operation has been a complete one, wounds of the soft parts may be closed by suture on or after the fourth day. The dressing applied in the evacuation hospital is removed under aseptic precautions in an operating room of a general hospital at the base. Following closure, the part is immobilized preferably by a light plaster encasement, or if this is impractical, by bed rest" (5).

A parallel evolution in wound management, differing only in unimportant details, took place in the Central Mediterranean Forces of our allies, with whom a close and cordial professional relationship was enjoyed from the time of the invasion of North Africa. Brigadier Harold C. Edwards (9) Consulting Surgeon A.F.H.Q. in a Report to the Director of Medical Services covering the period March 1 to October 31, 1944 referred to the subject as follows: "It is not too much to claim that the surgery of war wounds has undergone a radical change since the first mass experiment in delayed suture was planned before the battle of Cassino.

'The accepted treatment of all wounds as a two stage operation' irrespective of whether an open fracture exists or not. This conception has led to an immense diminution in invalidism as a result of chronic sepsis of pain and discomfort, and of numbers of dressings. It has led to an incalculable saving of hospital beds (one analysis has showed the saving to be

Italics by the writer

¹That deep instinct of the surgeon to anoint the wound with healing balms, salves or antiseptics and to keep it open with setons, tents or tubes, finds its roots in the mysticism and polypharmacy of the ancients. It still plagues our craft in the usage of the precise tools of chemotherapy and antibiotic agents. A long line of illustrious surgeons, basing their experience more often than not on the battlefield, have combatted the doctrine that the healing of a wound is governed by the topical applications of the surgeon. This line of dissenters extends from Lord Moynihan, the great sceptic of World War I, through Lister, Wurtz, Parré, Henry of Menderville, Hough of Lucca and Theodorick, Celsus, and the Good Samaritan, to Hippocrates.

SURGERY GYNECOLOGY AND OBSTETRICS

as 24-35) and in consequence of manpower Men are fighting now¹ who have already twice recovered from wounds since the 'D Day for Cassino—May 12th Furthermore the resulting scars have been firmer less adherent and less liable to break down

In the Royal Army Medical Corps the terms delayed suture and secondary suture were retained and the program as a whole referred to as the treatment of a wound by a two-stage operation.

The adjective *reparative* was chosen by the U S Army Medical Corps to set apart the phase of surgery under discussion from the initial operation (débridement) that precedes it and the reconstructive surgery that may follow. Reparative surgery has been referred to as surgery of necessity for a limited time exists following the initial surgery during which its maximum benefits may be secured. It is neither emergency surgery on the one hand, nor elective surgery in the sense that it may be postponed, on the other. The word *reparative* was chosen with reference to the technical procedures that repair damaged and distorted anatomic parts also it indicates that the surgery coincides with the period of greatest biologic activity in wound repair. This starts on the fourth day the time selected on purely clinical grounds as the optimal time for surgical repair of a soft tissue wound. There is no sharp end point, but for the simple wound the optimal phase for surgery closes at approximately the tenth day. This time interval for reparative surgery is fixed by biologic laws to which military planning must accede unless grim necessity demands sacrifice of that part of the potential combat strength of the force evacuated as lightly wounded.

The application of the procedures of reparative surgery requires an analysis of a wound in terms of the structures that have been damaged for the repair of each tissue and structure is subject to different laws. It also stimulates a precise analysis and recast of terminology to achieve uniformity in definition and clarity in thinking.

It is important that the scope of the term *reparative surgery* be clearly understood. It is by no means synonymous with *delayed*

primary suture, delayed suture, and secondary suture." Reparative surgery defines a phase of wound management during which these procedures, referred to as the second stage of the two-stage operation by Edwards, are carried out. In addition, other operations such as decortication of the lung, the early removal of foreign bodies, the repair of nerve injuries, and the final reduction of battle fractures are considered as reparative surgery because they are designed to prevent or cure short wound infection either before it is established or at the period of its inception or concerned with restoration of the function of the part by anatomic repair.

Wounds are referred to as *simple*² or *complex*³ soft tissue wounds when the injury is confined to skin, subcutaneous tissue and fascia, and muscle damage is not extensive. A *complex*³ wound has, in addition to the soft tissue wound, damage to nerve, bone, tendon, joint or major vascular trunk, or extensive damage to muscle that will materially interfere with function. In the management of a complex wound subsequent to the initial surgical débridement, separate consideration must be accorded each component part of the wound, such as the wound of the soft tissue, the wound of the bone or that of the nerve. The timing the sequence and the extent of the reparative surgical procedures carried out on a complex wound are determined by its component parts, their extent and nature, and the wide variety of combinations in which they may be present.

Thus the term *reparative surgery* designates a phase of wound surgery applicable to complex wounds as well as simple wounds.

¹The term *simple gunshot wound* was defined and used by G. J. Guthrie in recording the opinions and practice of the Medical Department of the British Army at the termination of the wars in Spain, Portugal, France, and the Netherlands, in this and Arty. Simple wounds were "Wounds in Parts of the body in portations or Comparative Consequence in the Human Frame." Various terms have been used to describe wounds that are more extensive than simple wounds. The adjective *compound*, is closely linked by usage with open injuries of bone and joint and has thereby acquired specialized significance. The term *fractured* implies "complex complications" such as secondary hemorrhage or infection and for this reason is best reserved for wounds with sequential pathologic entry. Also, specialized meaning has developed in bone and joint surgery and *compound* fractures is one with adjacent injury to other structures such as nerve or joint. In the sense used here, *complex wound* is one which multiple and important anatomic components that are involved. It contrasts neatly with the simple wound of the military reports of the past.

rather than any single technical procedure such as delayed suture of the soft tissues. It includes a wide variety of operative procedures for complex wounds as well as closure of the skin and underlying soft tissue. Also as a comprehensive term it includes a number of methods of closure of simple wounds that find a constant application when large numbers of casualties are being treated. The terms 'delayed primary suture' and 'secondary suture' describe the closure of the skin in terms of the time interval that has elapsed before closure is attempted. Universal agreement is lacking as to the actual time intervals that are implied by the use of these two terms and experience has shown that, after all, no sharp line exists so far as the ultimate result is concerned provided the surgical technique employed is adapted to the specific problem at hand. For this reason the inclusive term 'reparative suture' has come into use implying a delay and contrasting with primary suture.

In general the following principles will be found valid in the management of a simple wound or the soft tissue component of a complex wound.

1. When the initial surgery (débridement) has been complete and the wound has been protected from subsequent contamination by an occlusive dressing and adequate splinting the optimal time for closure is the fourth post-operative day. At this time muscles and fascial planes may be sutured with catgut, cotton or silk, and closure of the skin defect may be aided by the advancement or rotation of flaps or the application of a split thickness graft.

2. As the time interval is increased beyond the fourth day, the feasibility of anatomic layer closure diminishes and there is a steadily increasing number of cases in which closure must be performed by single sutures passing through all layers.

3. On or about the tenth day it will be found necessary to undercut the cutaneous margins, with or without the removal of surface granulation tissue to obtain skin approximation. The incidence of kindly healing will be appreciably lessened and the ultimate scar will tend to spread.

4. Again as the time interval is extended beyond the fourth day there will be found an

increasing indication completely to excise the wound before suture thus to restore flexibility and permit layer closure. This procedure is limited to wounds in anatomic regions where additional loss of tissue will not interfere with the ultimate functional or esthetic result. In very late wounds (3 weeks to 6 months) complete wound excision is an essential prelude to closure by suture and may be necessary or advisable preceding skin grafting.

5. When the initial surgery (débridement) has not been complete and devitalized tissue remains in the wound a purulent exudate at times associated with a foul odor will be apparent by the fourth day. Under these circumstances the residual necrotic tissue may be excised and the wound closed immediately or following excision the wound again may be left open and closure undertaken when it is certain that all dead tissue has been removed and invasive infection is not to be reckoned with.

6. When invasive infection is present, free drainage is established and tissue devitalized by the infection or by the original trauma is excised. The interval before closure may be attempted varies with the severity and extent of the infection but usually falls within the 10 day period following the operation.

Management of the soft tissue component of a complex wound is modified by the treatment that must be directed to those injured structures that are important to the ultimate function of the part. In a complex wound the goal of reparative surgery is not limited to the closure of the soft tissues and skin but extends to the repair of the wound of the bone, the nerve or the important muscles that have been divided. In general early closure of the skin is greatly desired to exclude further bacterial contamination but it may be delayed deliberately. For example following reparative suture of a transversely divided quadriceps femoris or deltoid muscle the skin may be left unsutured in selected cases to provide free escape for blood and wound exudate. Skin closure is then carried out in approximately 4 days. Battle fractures are complex wounds and usually the most important component of the wound is the fracture rather than the soft tissue defect. After accurate re

duction is secured closure of the muscles over the fracture site is the most vital step of reparative surgery. Suture of the skin may be delayed, or if the defect is small, spontaneous healing may be anticipated long before the fracture is united. Again complete or partial division of a nerve may be the most important component of a wound. Here the first step may be complete suture of the soft tissues and skin to obtain clean healing with minimal scar formation. Repair of the nerve then may be undertaken at a 3 week interval. When nerve and bone are both injured still more elaborately staged procedures may be indicated, always with the goal of the restoration of the ultimate function of the extremity in mind.

The surgical principle that has emerged may be summarized as follows. Following an open traumatic injury excision of dead and devitalized tissues should be done at the earliest opportunity. This may be considered as an initial operation and care is taken to conserve all viable parts that are important to subsequent function. Dressings and splinting are designed to minimize swelling and prevent further damage to structures by motion. Invasive infection is held in check by systemic chemotherapy. The patient may then be transported to receive the full benefit of whatever specialized technical skills are required for the reparative surgery of complex injuries. The application of this principle in civilian trauma is readily apparent.

THE PATTERN OF TRAUMA

The war experience with traumatic injury emphasizes the need for further understanding of what may be called the pattern of trauma. When individuals are simultaneously subjected to trauma or sequentially exposed to the same trauma, the resulting injuries conform to a type pattern. This has long been recognized in civilian injuries, and entities such as miners' elbow and bumper fracture are surgical classics. It is a familiar finding in disasters and I need only mention the Cleveland Clinic fire and the Boston Coconut Grove fire to emphasize the necessity for immediate recognition of the pattern of trauma. There were similar incidents during the war such as the Bari air raid and of course most

notably the atomic bomb attacks on Hiroshima and Nagasaki. Recognition of the pattern of trauma must be prompt in disaster to point the way toward effective treatment of the survivors. A recurring pattern in injuries sustained sequentially under similar circumstances leads the surgeon to propose preventive measures.

PREVENTIVE SURGERY

World War II witnessed a rudimentary but clear appreciation of preventive surgery as an undeveloped phase of our craft. Preliminary explorations were made in the use of protective armor against flying missiles. Protective body armor in the form of a "flak suit" was adopted early by the Air Force. Careful analyses on the lethality of weapons and the distribution of wounds document the assertion by DeBakey (8) that the application of existing knowledge on body armor might "reasonably be expected to reduce the number of those killed in action by 12 per cent and of those wounded in action by 8 per cent. Although the war ended before body armor could be used in any area of land combat, other protective devices, in addition to the familiar steel helmet, were introduced by surgeons. Sir Alexander Hood (11) points out that the familiar crash helmet of the British Army was designed by a neurosurgeon (Hugh Cairns). Surgeons of the European Theater of Operations (7) assisted the medical service of the Air Force in a vigorous effort to prevent high altitude frostbite. With protective equipment and procedures this crippling injury of expert bomber crews was virtually eliminated. Ophthalmologists conducted extensive field studies on the use of shields designed to protect the eyes from the hazards of land mine and booby trap explosions.

The control and prevention of blast injuries of the ears were effected by joint study of Ordnance and the National Research Council. The incidence of aero-otitis, a common disability that grounded highly trained air crews was greatly reduced by control measures. Footgear effective in the prevention of trench foot was developed through Medical Department liaison with the Quartermaster. Tetanus, an ancient scourge of the battlefield, was vir-

tually eliminated by the inoculation with toxoid.

It is clear that this preventive phase of surgery must be developed with vigor and imagination to keep pace with the traumatic hazards of modern life. Or surgery will remain solely a salvage service. Although the surgeon is historically the senior practitioner of the battlefield, his place of importance has been yielded to the expert in preventive medicine in the conflict of mass armies. With the awful increase in the lethality of weapons and the destruction of the civilian population as the strategic objective of the enemy, it seems unlikely that military surgery will ever regain its ancient position by virtue of its salvage func-

tion alone. As the military power of this country depends upon highly specialized personnel operating extremely complicated weapons and machines, the military surgeon of the future must be an expert in the prevention of traumatic injury in addition to its alleviation.

THE DOCTOR AT WAR

Having discussed certain ways in which his war experience may have modified surgical theory and concept, I shall deal briefly with broader phases of the experience of the American Surgeon A U S. Pearl Harbor found the civilian medical profession in a maze of poorly integrated but highly developed specialism in remedial medicine. The prevailing tactical

There were many lessons of the first World War that were promptly forgotten or the significance of which at the time were really not appreciated. In looking back at the experience of World War I with the perspective of the recent war there is no single item that has more profound significance than the position occupied by Franklin H. Martin as the representative of the medical profession during the first conflict. It contrasts with the lack of a medical statesman at that level in World War II. On October 11, 1916, President Woodrow Wilson appointed Franklin H. Martin to the Advisory Commission of The Council Of National Defense. The story is graphically told by the pen of Dr. Martin (17) himself in his *Digest of the Proceedings of the Council of National Defense during the World War*. Representation of the profession in an advisory capacity at the Cabinet level insured that the voice of Medicine could be heard.

In this respect I would be remiss not to pay sincere and deserved tribute to our own Dr. Fred W. Rankin. Without the strategic advantage of position granted to Dr. Martin in World War I it was inevitable that General Rankin's well designed efforts should meet with frustration time and time again. Nevertheless, by skillful and untiring efforts as Chief Surgical Consultant he stands out as the Sponsor of the American Surgeon A U S and the corner

stone upon which the achievements of American Surgery in World War II were erected.

TABLE I — COMPARISON OF THE INCIDENCE OF THE CAUSES OF DEATH IN PENETRATING WOUNDS OF THE ABDOMEN BEFORE AND AFTER CHEMOTHERAPY

1 cases admitted between January 1938 and January 1942			6 cases admitted between January 1942 and May 1946		
Per cent			Per cent		
Mortality rate			Mortality rate		
27.9			11.6		
Cases	no.	Per cent	Cases	no.	Per cent
Causes of death			Causes of death		
Peritonitis	9	31.0	Hemorrhage	7	30.4
Hemorrhage	7	24.1	Pneumonia	4	17.4
Shock	6	21.3	Putrefactive	4	17.4
Pneumonia	5	17.2	Empyema	4	17.4
Uremia	1	3.4	Peritonitis	3	8.7
Retroperitoneal cellulitis	1	3.4	Meningitis	2	8.7
			Uremia	1	4.3
			Undetermined	1	4.3

death in only 2 instances in the patients treated with sulfonamides. There is also evidence that systemic sulfadiazine therapy has had a similar beneficial effect in operations for resection of the bowel by greatly reducing the incidence of postoperative peritonitis

THERAPEUSIS

The value of sulfonamide therapy has been unquestionably established in acute infections produced by a hemolytic streptococcus the pneumococcus and the gonococcus but it is of little or no value in those caused by the hemolytic staphylococcus (2, 4, 12, 13, 18). Its advantages of low cost, ease of administration and high bacteriostatic action often make it the drug of choice in these infections.

Sulfadiazine is still a valuable drug in certain mixed infections produced by various gram negative and gram positive bacteria of the intestinal tract. *In vitro* studies on examples of mixed bacterial flora show that its marked bacteriostatic action is usually superior to that of penicillin in the usual concentrations which are built up in the blood during systemic therapy (Fig. 1). Clinical experience has likewise demonstrated the effectiveness of this form of chemotherapy in mixed infections. More recently very large doses of penicillin have proved to be very effective in the management of mixed infections. However certain limitations of sulfonamide therapy have become increasingly apparent including (1) the presence of bacterial species and group resistance (2) the inactivation of bacterio-

Fig. 1. Blood agar plate showing the superior bacteriostatic effect *in vitro* of sulfadiazine over that of penicillin on a mixed culture of both gram negative and gram positive bacteria. *Pseudomonas aeruginosa*, *Staphylococcus aureus*, resistant to penicillin. *Escherichia coli*, *Streptococcus viridans*, resistant to penicillin. Hemolytic streptococcus, susceptible to penicillin. *Staphylococcus aureus*, susceptible to penicillin. Nonhemolytic streptococcus, resistant to penicillin.

static activity by inhibitors found in pus wound exudates and necrotic tissue (3) the development of drug fastness by many of the infecting bacteria (4) the occurrence of some toxic reactions when its administration was not carefully controlled (5) its inability to penetrate areas of pus and necrosis and (6) the occasional occurrence of drug idiosyncrasy.

With the introduction of penicillin many of these limitations have been overcome. The sulfonamide inhibitors have little or no effect on the bacteriostatic action of penicillin and its extremely low toxicity has been of equal significance. Doses of one million units every 3 hours have been used repeatedly and in one instance a child received 100,000,000 units each 24 hours for 2 weeks without evidence of toxicity (13). The toxic reactions that have occurred during penicillin therapy have been due largely to impurities or idiosyncrasies and the threshold of toxicity as yet is undetermined.

At the present time penicillin is the most effective chemotherapeutic agent available for the treatment of many surgical infections particularly those caused by the staphylococci, the aerobic streptococci, the gonococci and the anaerobic streptococci. Evidence of its superiority over the various sulfonamides in the therapy of staphylococcal infections is overwhelming and its effectiveness in infections caused by sulfonamide-resistant strains of the streptococcus and gonococcus have been outstanding. The micro-organisms sensitive to its action *in vitro* are listed in Table II and

TABLE II.—PENICILLIN ACTIVITY IN VITRO—SENSITIVE MICRO-ORGANISMS

<i>Gonococcus</i>	<i>Clostridium histolyticum</i>
<i>Alteromonas</i>	<i>Clostridium septicum</i>
<i>Streptococcus</i>	<i>Clostridium sordelli</i>
hemolytic	<i>Clostridium oedematis</i>
viridans	<i>Clostridium sporogenes</i>
microaerophilic	<i>Clostridium bisfermentans</i>
anaerobic	<i>Bacillus diphtheriae</i>
<i>Staphylococcus</i>	<i>Bacillus pseudodiphtheriae</i>
aureus	<i>Lactobacillus</i>
albus	<i>Cryptococcus hominis</i>
anaerobic	<i>Spirillum minus</i>
<i>Micrococc</i>	<i>Streptobacillus moniliformis</i>
<i>Pneumococcus</i>	<i>Treponema pallidum</i>
<i>Bacillus subtilis</i>	<i>Bacillus alkaligenes</i> (some strains)
<i>Bacillus anthracis</i>	<i>Leptospira icterohemorrhagiae</i>
<i>Actinomyces bovis</i>	<i>Erysipelothrix rhusiopathiae</i>
<i>Clostridium tetani</i>	
<i>Clostridium tetanomorphum</i>	
<i>Clostridium botulinum</i>	
<i>Clostridium welchii</i>	

those resistant in Table III. More recently the very low toxicity of penicillin has permitted exploration of the clinical value of very large doses in infections produced by bacteria resistant or slightly susceptible to its action. The encouraging results obtained justify a more thorough investigation of the therapeutic possibilities of large doses up to one million or more units every 3 hours in this type of infection.

In the 4 years between November 1942 and November 1946 704 surgical infections treated with penicillin surgery when indicated and the general and local supportive measures for correction of altered physiology have been studied and they included the following:

Staphylococcal infections	47
Pneumococcal infections	70
Anaerobic streptococcal infections	
Aerobic streptococcal infections	80
Gonococcal infections	40
Actinomycotic infections	7
Human bit infections	9
Ratbite fever infections	8
Gas gangrene infections	
Pyoderma gangrenosum infections	4

Experience has shown that penicillin is the chemotherapeutic agent of choice in the treatment of all staphylococcal infections in surgery having replaced all previous forms of chemotherapy. An arbitrary tabulation of the clinical results obtained with penicillin in the treatment of the 427 cases with established staphylococcal infections is given in Table IV.

TABLE III.—PENICILLIN ACTIVITY IN VITRO—RESISTANT OR SLIGHTLY SUSCEPTIBLE STRAINS OF MICRO-ORGANISMS

<i>Bacillus coli</i>	<i>Acne bacilli</i>
<i>H. influenzae</i>	<i>M. tuberculosis</i>
<i>Bacillus typhosus</i>	<i>Bacillus thuringiensis</i>
<i>Bacillus paratyphosus</i>	<i>Brucella abortus</i>
<i>Bacillus dysenteriae</i>	<i>Brucella melitensis</i>
<i>Bacillus proteus</i>	<i>Bacillus melitensis</i>
<i>Bacillus enteritidis</i>	<i>Moraxella axioma</i>
<i>Bacillus pyocyaneus</i>	<i>Moraxella candelae</i>
<i>Aerobacter aerogenes</i>	<i>Blastomycetes</i>
<i>Bacillus floccosus</i>	<i>Toropiletes</i>
<i>Bacillus friedlanderi</i>	<i>Bacillus mycoides</i>
<i>Bacillus prodigiosus</i>	<i>Lymphophilus coccineus</i>
<i>Bacillus pastis</i>	<i>virus</i>
<i>Vibrio cholerae</i>	

The effects of penicillin therapy were particularly apparent in the treatment of the severe staphylococcal infections with invasive manifestations. If the infection was in the diffuse or cellulitic stage, penicillin therapy was often followed by complete and spontaneous resolution and a minimal amount of local destruction of tissue (Fig 2). If the diagnosis

TABLE IV.—RESULTS IN PENICILLIN THERAPY—STAPHYLOCOCCAL INFECTIONS

Clinical Diagnosis	No. cases	Results
